ABSTRACT

7
8 Hydroclimate in Western North America (WNA) is highly seasonal, with ecological and so-
9 cial systems finely tuned to within year variations in moisture availability. Here, 21st century
10 century climate model projections are used to assess seasonal changes in precipitation, evap-
11 otranspiration, and runoff in response to greenhouse gas warming across the diverse climates
12 of WNA. Winter precipitation increases across most of WNA, but declines sharply in Mexico.
13 During the spring, precipitation increases in the Northwest and Northern Plains and the dry-
14 ing in Mexico expands northward into the Southwest and California. Summer precipitation
15 decreases over the Great Plains, the Pacific Northwest, and during July in the North Amer-
16 ican Monsoon region; this delay in the monsoon is largely compensated by increased late
17 monsoon (September) precipitation. For most regions of WNA, these precipitation changes
18 manifest as an amplification of precipitation seasonality (i.e., wetter wet seasons, drier dry
19 seasons) and are forced by changes in moisture convergence due to changes in the mean flow
20 or transient eddy activity. Even in areas where total winter precipitation (rain and snow)
21 increases, snowfall is reduced, especially over the Montane West and Northwest Coastal re-
22 gions. This shift from snow to rain, combined with increased spring-time evapotranspiration,
23 increases runoff during the winter and decreases runoff in the spring. Notably, these large
24 seasonal trends in precipitation and runoff over the 21st century are masked or obfuscated
25 over much of WNA when integrated over the entire calendar year. Adaptation decisions will
26 therefore need to account not only for declines in total water resources, but also shifts in
27 hydroclimate within the calendar year.

1. Introduction

Climate change is a significant challenge for water resource management in Western North America (WNA) (e.g., Gleick 2010; MacDonald 2010; Scanlon et al. 2012). In this region, warming from increased greenhouse gas (GHG) forcing is expected to increase evaporative demand (Scheff and Frierson 2013), shift precipitation patterns (Seager and Vecchi 2010; Seager et al. 2013), and cause declines in runoff and streamflow (Hagemann et al. 2013; Schewe et al. 2013). Concerns about climate change in WNA have been amplified by several recent drought events, including Texas and northern Mexico in 2011 (Hoerling et al. 2012; Seager et al. 2014 in review), the Central Plains in 2012 (Hoerling et al. 2014), and the ongoing, chronic drought in the Southwest that began in 1998 (Cayan et al. 2010; Seager 2007; Weiss et al. 2009). But while climate model projections have been broadly analyzed to assess general declines in precipitation and water resources in WNA (e.g., Cayan et al. 2010; Seager et al. 2014 in review), little work has been done to comprehensively assess the seasonality of hydroclimate trends across the entire WNA domain.

Hydroclimate in WNA is highly seasonal (Markham 1970), perhaps best characterized by the pronounced wet and dry seasons evident in the seasonal distribution of precipitation (Figure 1, data from Schneider et al. 2014). In the coastal regions of the Northwest (127°W–118°W, 42°N–50°N) and Southwest (127°W–118°W, 33°N–42°N), most precipitation falls during the winter and spring (October–March). At lower elevations, where most precipitation falls as rain, annual peak runoff and reservoir inflow closely follow this annual precipitation maximum (Chang and Jung 2010; Dettinger et al. 2011). At higher elevations, where more precipitation occurs as snow, runoff and streamflow peaks shift later in the

50 year, coinciding with the spring snow melt pulse (Aguado et al. 1992). Precipitation in the
51 Montane West (118°W–106°W, 35°N–45°N), by contrast, has a more uniform seasonal dis-
52 tribution (Markham 1970; Mock 1996). In this area, most winter precipitation falls as snow,
53 which accumulates and melts in the spring to drive the annual spring discharge peak and fill-
54 ing of reservoirs in rivers like the Colorado and upper basin of the Rio Grande (Christensen
55 et al. 2004; Dahm et al. 2005). In the Northern (114°W–96°W, 45°N–53°N) and Central
56 Plains (104°W–95°W, 30°N–45°N), peak annual precipitation occurs in the late spring and
57 early summer. Modest snowfall during the winter, combined with this late spring/early
58 summer precipitation peak, both contribute to spring-time maxima in runoff, especially for
59 more northern rivers (e.g., the Red River in North Dakota, Stoner et al. 1993). Finally,
60 the North American Monsoon region (112°W–102°W, 18°N–33°N) receives most of its pre-
61 cipitation during the late summer and early fall. Here, over 70% of annual precipitation
62 falls in July-August-September, causing large runoff peaks and river flows in September and
63 October (Adams and Comrie 1997).

64 Even with no change in total annual water resources, shifts in hydroclimate and wa-
65 ter availability at the seasonal scale can significantly impact the functioning of ecosystems
66 and societies. Warm and cold season precipitation often satisfy different societal demands
67 (e.g., reservoir supply vs dryland agriculture and ranching; Woodhouse et al. 2013), fire and
68 ecosystem disturbance regimes are sensitive to the timing and amount of precipitation (Ray
69 et al. 2007; Swetnam and Betancourt 1998), and shifts in runoff often require tradeoffs be-
70 tween managing reservoirs for flood control versus storage (Aguado et al. 1992; Dettinger
71 et al. 2011). Given the clear ecological and social consequences of seasonal changes in WNA
72 hydroclimate, it is therefore important to understand how and why these shifts will occur

73 under global warming. To address this goal, we use climate projections from the Coupled
74 Model Intercomparison Project version 5 (CMIP5, Taylor et al. 2012) to comprehensively
75 analyze the seasonal response of hydroclimate in WNA over the 21st century. We expand
76 on previous work (e.g., Cayan et al. 2010; Seager et al. 2013, 2014 in review) by focusing on
77 the main terms in the surface moisture budget (precipitation, evapotranspiration, runoff) at
78 the seasonal scale and across the diverse climates of WNA.

79 **2. Methods and Data**

80 *a. CMIP5 Models*

81 Our analyses use model output (1980–2099) from the historical and RCP 8.5 model scenarios
82 in the CMIP5 archive (Taylor et al. 2012). The historical simulations use observationally
83 derived climate forcings (e.g., solar, aerosols, greenhouse gases, etc) to force coupled ocean-
84 atmosphere model simulations from 1850–2005. Simulations under the RCP 8.5 scenario are
85 initialized using the end of the historical runs, and represent the high end of the suite of
86 possible future GHG forcing scenarios. In RCP 8.5, the simulations are designed to have an
87 approximate global radiative imbalance of $+8.5 \text{ W m}^{-2}$ at 2100. Use of RCP 8.5, rather than
88 a lower emissions scenario, is appropriate, given the current lack of any serious international
89 effort to mitigate GHG emissions.

90 We focus on variables that make up the surface moisture balance and are most relevant
91 from an impacts and resource use perspective: precipitation (rain and snow), evapotranspi-
92 ration, and runoff (surface and subsurface). Total precipitation (rain and snow) represents

93 the moisture supply side of the surface moisture budget, which is then lost from the soil
94 either vertically to the atmosphere (via evapotranspiration) or horizontally (via surface or
95 subsurface runoff). Evapotranspiration rates depend on both the atmospheric demand for
96 moisture (potential evapotranspiration), which is expected to increase with GHG warming,
97 and soil moisture availability, which may increase or decrease depending on supply and de-
98 mand changes. Runoff is an especially important variable from a resource use perspective, as
99 it represents the total sustainable water supply (excluding renewable groundwater) available
100 for use by local human populations (e.g., Murray et al. 2012; Postel et al. 1996; Vörösmarty
101 et al. 2000). Runoff, and its seasonal cycle, is also critical for the ecological vitality of riparian
102 ecosystems (Perry et al. 2012; Rood et al. 2008). We did not analyze soil moisture changes,
103 because of the paucity of models that provided level-by-level soil moisture diagnostics for
104 the RCP 8.5 simulations in the CMIP5 archive. Our analysis is therefore restricted to those
105 models with continuous (historical to RCP 8.5) ensemble members (Table 1) that provide
106 these hydroclimate diagnostics. With this criteria, we were able to analyze 22 total models,
107 8 of which have multiple ensemble members.

108 *b. Analysis*

109 The six regions of WNA that we focus on are: the Northwest Coast, the Southwest Coast, the
110 Montane West, the Northern Plains, the Central Plains, and the North American Monsoon.
111 These regions were chosen based on their distinct hydroclimate regimes and importance of
112 water resources for local ecosystems, agriculture, and societies. These regions, including their
113 hydroclimatology, are described in the Introduction and are indicated by the dashed boxes

114 in Figure 1 and subsequent figures. For the spatial comparisons, all model diagnostics are
115 interpolated to a common 2° latitude/longitude grid. Within model ensemble averages are
116 calculated before calculating the multi-model means so that each model is weighted equally.
117 For the maps, areas where the multi-model ensemble shows *robust* changes, defined as at
118 least 18 of 22 (80%) of individual models agreeing with the sign of the multi-model mean
119 change, are indicated with a black x. For precipitation, snowfall, evapotranspiration, and
120 runoff, areas where changes in the multi-model mean are small ($< 5\%$) are masked in gray,
121 regardless of whether these changes are robust across models or not. For other plots, the
122 multi-model mean is indicated by either a solid black line or colored bar, and the multi-
123 model ensemble spread (± 1 standard deviation) is shown by gray shading (line plots) or
124 whiskers (bar plots). Seasonal averages are based on the water year (October-September),
125 rather than the calendar year. We analyze changes in hydroclimate for two different 21st
126 century intervals: 2030–2049 and 2080–2099, both relative to the historical model scenario
127 baseline of 1980–1999. The historical baseline period is chosen so that projections reflect
128 changes relative to the modern climate. For future projections, the later period (2080–2099)
129 is chosen because the climate change signal is largest and clearest, while the former period
130 (2030–2049) is more relevant to current and future efforts to develop plans for adaptation to
131 climate change.

132 **3. Projected changes in hydroclimate seasonality across** 133 **North America**

134 *a. Spatial Patterns*

135 Robust changes in annual average precipitation occur over Mexico (drier), the Eastern United
136 States (wetter), and the northern half of North America (wetter) (Figure 2a,b). Changes
137 in annual runoff are less robust (Figure 2c,d), increasing in the Northwest and Northeast
138 and declining in a narrow band extending from Mexico up through New Mexico, Texas, and
139 Colorado. Despite these large localized changes, annual average shifts in precipitation and
140 runoff are small or non-robust across much of WNA.

141 Seasonal changes in hydroclimate are larger and more spatially extensive. Tempera-
142 ture (Figure 3) and precipitation (rain and snow, Figure 4) changes in our multi-model
143 ensemble are generally consistent with other analyses of the CMIP5 model projections (e.g.,
144 Knutti and Sedlacek 2013). The temperature response is one of uniform and robust warm-
145 ing across the entire continent, with the largest magnitude of warming at high latitudes
146 during the winter (JFM). The models also show hotspots of amplified warming in certain
147 WNA regions, including the Montane West, Central Plains, and North American Monsoon.
148 Precipitation reductions are most widespread and robust across models during winter and
149 spring (AMJ). In winter, these declines are confined primarily to southern Arizona, New
150 Mexico, Texas, Mexico, and Central America. By the spring this drying spreads northwest
151 into Arizona, New Mexico, Colorado, Utah, Nevada, and California. During summer (JAS)
152 and fall (OND), areas of reduced precipitation are less extensive, and in JAS, shifted north-

153 ward to the Northwest Coast, and Central and Northern Plains. Widespread increases in
154 precipitation are apparent across the fall, winter, and spring seasons over the northern half
155 of the continent.

156 Despite increases in cold season total precipitation over broad areas (Figure 4), the
157 amount falling as snow actually decreases across much of North America (Figure 5). The
158 most widespread and robust declines occur in late fall/early winter (November-December)
159 and late winter/early spring, seasons when warming can shorten the time when temperatures
160 are ideal for snow (March-April). Largest declines in snowfall span from the West Coast and
161 Montane West regions across the continent and into the Northeast. Increases in snowfall
162 are confined to the most northerly latitudes around Hudson Bay, with little change in the
163 Northern Plains during the core winter season (January-February).

164 Evapotranspiration increases over most of North America (Figure 6) in areas where mois-
165 ture supply at the surface is sufficient to keep pace with the increased evaporative demand of
166 a warmer atmosphere (Figure 3). Robust declines in evapotranspiration are confined primar-
167 ily to the Southwest and Mexico; despite increases in evaporative demand, these are areas
168 where soil moisture is expected to decline to the point that evapotranspiration rates become
169 limited by soil moisture supply versus atmospheric demand (e.g., Seager et al. 2013). The
170 largest runoff declines occur during the spring (Figure 7), spanning a broad area from the
171 Northwest Coast, through California and the Montane West, and into the Southwest and
172 Mexico. At high Northern latitudes, runoff increases during fall and winter, in step with
173 large precipitation increases in these areas. Winter also sees modest increases in runoff over
174 the Northwest and Southwest Coastal regions.

175 *b. The Southwest and Northwest Coastal Regions*

176 For the Southwest and Northwest coastal regions (Figure 8), the model precipitation cli-
177 matologies (black lines, 1980–1999) closely match the observed climatology (blue lines) cal-
178 culated from version 6 of the Global Precipitation Climatology Centre (GPCC, Schneider
179 et al. 2014). Both the models and observations show the wet winter and dry summer seasonal
180 pattern typical of the West Coast. Biases in the model precipitation are positive for nearly
181 all months, especially during the winter along the Southwest Coast. Model snowfall in these
182 regions is only a minor fraction of total winter precipitation, resulting in highest runoff dur-
183 ing February and March. Evapotranspiration peaks in the spring and early summer, when
184 evaporative demand is high and surface moisture is still available.

185 Over the 21st century, precipitation is projected to increase during January and Febru-
186 ary along the Southwest Coast and from November through February in the Northwest
187 (Figure 9), declining in the spring (April–May) in the Southwest and during the summer
188 (July–August) in the Northwest. Despite the wet season getting wetter in terms of total
189 precipitation, both regions experience large declines in the amount of precipitation falling as
190 snow. For the Southwest coast the reductions are sufficient to actually reduce the number of
191 months that this region experiences snow (cf. the snow fall climatology in Figure 8). With
192 the winter precipitation increases and the increased evaporative demand from the warmer
193 atmosphere, evapotranspiration rates also increase in the first 3–6 months of the calendar
194 year. As a result of the precipitation, snow, and evapotranspiration changes, the seasonal
195 cycle of runoff shifts earlier in the year: increasing in January-February (increased precipi-
196 tation and more falling as rain) and decreasing in April-May (increased evapotranspiration,

197 modestly reduced precipitation, and less snow pack storage carrying over from the winter).

198 *c. The Northern and Central Plains*

199 The model ensemble has a slight positive precipitation bias over the Northern and Central
200 Plains, but otherwise the precipitation seasonality is well resolved by the models (Figure
201 10). Total precipitation is relatively low in the winter months compared to the warm season,
202 but most winter precipitation falls as snow, especially in the Northern Plains. Evapotran-
203 spiration rates in the Plains regions peak in the late spring and early summer (May-July).
204 In the Northern Plains, model runoff peaks in March and April, when the winter snow pack
205 melts and evapotranspiration rates are low, consistent with streamflow observations in this
206 region. In the Central Plains, peak runoff is shifted later and coincides more closely with
207 the spring precipitation maxima, although there is a broad cross-model spread in simulated
208 runoff for this region.

209 In the Northern Plains, precipitation increases in April-May, followed by robust reduc-
210 tions during July and August; a similar pattern is also seen for the Central Plains (Figure
211 11). These seasonal shifts in precipitation point to an overall intensification of the seasonal
212 cycle of precipitation in this region (i.e., wetter springs and drier summers). Despite increases
213 in total winter and spring precipitation, snowfall declines in all months. Evapotranspiration
214 shifts follow changes in precipitation, with increases in winter and spring and declines over
215 the summer, pointing to the importance of both evaporative demand and moisture supply
216 controls on evapotranspiration rates in these regions. Runoff changes are small or negligi-
217 ble for most months in the Northern Plains region; increases are apparent in January and

218 February, followed by declines in the spring (March-April). In the Central Plains, runoff
219 decreases in nearly all months.

220 *d. The Montane West and The North American Monsoon Region*

221 For the Montane West and North American Monsoon regions, the models have substantial
222 positive precipitation biases, especially during the winter in the North American Monsoon
223 region and all year in the Montane West (Figure 12). Model wet biases in the Montane
224 West may be caused by the relatively coarse horizontal resolutions of the GCMs, hampering
225 the ability of the models to resolve the Sierra Nevada and Cascade mountain ranges and
226 the necessary orographic effects on precipitation. Alternatively, the large mismatch in the
227 Montane West may be due at least partially to problems in the observations, rather than the
228 models. For example, precipitation datasets are known to have deficiencies in mountainous
229 areas because of snow undercatch and station placement lower than most of the topography
230 (e.g., Bosilovich et al. 2008; Legates and DeLiberty 1993), which may lead to large underesti-
231 mates of precipitation. Comparisons we conducted against other precipitation datasets (e.g.,
232 PRISM) show similar, but less severe, dry biases in the observations (not shown). Over the
233 North American Monsoon region the models also have difficulty capturing the rapid seasonal
234 transitions into and out of the main monsoon season (July–September, Adams and Comrie
235 1997). Despite these differences, the models reasonably capture the seasonality, with pre-
236 cipitation evenly distributed throughout the year in the Montane West and concentrated
237 during the summer in the North American Monsoon. In the Montane West, snow makes
238 up most of the model winter precipitation, with subsequent melt in the spring leading to a

239 pronounced runoff peak in March-April-May. Winter precipitation falls almost entirely as
240 rain in the North American Monsoon region, causing a small runoff peak during the winter
241 that is secondary to the dominant peak in August and September that follows the monsoon
242 season rains.

243 Total winter precipitation increases in the Montane West (Figure 13), but this is matched
244 by an almost equivalent decline in snowfall, indicating, as with other regions of WNA, an
245 increased proportion of precipitation falling as rain rather than snow. The shift from snow
246 to rain, combined with increased evapotranspiration during the spring, leads to a shift in
247 runoff from spring (decreased) to winter (increased). The North American Monsoon region
248 shows clear and consistent declines in precipitation in the winter and spring, forcing a large
249 reduction in evapotranspiration during the spring. During the monsoon season, however,
250 there is a decline in precipitation during the early part of the monsoon (July), and a gen-
251 eral increase towards the end (September), indicating a delayed onset and withdrawal of
252 the monsoon. Overall, the declines in winter and spring precipitation in this region lead to
253 declines in runoff, especially during the winter and spring seasons.

254 *e. Relationship to changes in atmospheric moisture budget and circulation*

255 The diverse precipitation response in the models across regions and seasons can be attributed
256 to various dynamic and thermodynamic mechanisms; a comprehensive analysis of these pro-
257 cesses for North American precipitation trends in the CMIP5 projections is described in
258 Seager et al. (2014 in review). To investigate these mechanisms in the context of our ensem-
259 ble mean precipitation changes, we calculated climatologies and changes in mean flow and

260 transient eddy moisture convergence for our three month seasonal composites. Only 17 (in-
261 dicated by * in Table 1) of our original 22 models provided the necessary diagnostics. Areas
262 of robust cross-model agreement for these variables are based on 13 of the 17 models. Seager
263 et al. (2014 in review) compare the multimodel ensemble mean CMIP5 moisture budget
264 with that in the European Centre for Medium Range Weather Forecasts Interim Reanalysis
265 (ERA-I) and show a quite high level of model fidelity in simulating the main features.

266 As with other components of western hydroclimate, there is substantial seasonality in
267 moisture convergence, illustrated by the climatology from the multi-model mean of our his-
268 torical ensemble (Figure 14, 1980–1999). Transient eddies and the mean flow both converge
269 moisture along the west coast during the cold season (OND and JFM). In the same sea-
270 sons, the mean flow diverges moisture out of the Southwest and North American Monsoon
271 region. During spring and summer, this region of mean flow divergence expands and shifts
272 north, suppressing precipitation and drying California and the Montane West. Over the Cen-
273 tral Plains and North American Monsoon regions, mean flow and transient eddy transports
274 change sign during the observed seasonal cycle, with the mean flow converging moisture dur-
275 ing the spring and summer wet seasons and diverging moisture during the fall and winter in
276 these regions and with the transient eddies generally opposing the mean flow contribution.

277 Changes in the moisture convergence terms by the end of the 21st century generally reflect
278 an intensification of these patterns (Figure 15). Reductions in cold season (OND and JFM)
279 precipitation over Mexico and the Southwest are caused primarily by enhanced mean flow
280 divergence. Following the climatology, in the spring (AMJ) the center of enhanced mean flow
281 divergence shifts and spreads north, allowing the drying to expand across the Montane West
282 and West Coast. Changes in the mean flow also drive the intensification of precipitation sea-

283 sonality in the Northwest, with enhanced mean flow moisture convergence in OND and JFM
284 in this region (the wet season), followed by anomalous divergence that persists through the
285 spring and summer (the dry season). While mean flow shifts dominate precipitation changes
286 over the far western half of the continent, changes in transient eddy moisture fluxes are the
287 main actor in the Plains regions. In JFM, precipitation increases in the Northern Plains
288 because of increased moisture convergence by transient eddies, while during JAS the mean
289 pattern of transient eddy moisture convergence (centered in eastern Mexico) and divergence
290 (from Plains and east) intensifies and shifts northward, drying out the Central and Northern
291 Plains. As shown in Seager et al. (2014 in review), the intensifications of transient eddy
292 moisture convergences and divergences arises not from stronger eddy fields (at lower levels
293 they actually weaken) but from the intensified moisture gradients expected with a warming
294 atmosphere than can hold more moisture. Changes in transient eddy activity during OND
295 break the broad tendency in the models to intensify the climatology with GHG warming.
296 During this season, anomalous convergence in eastern Mexico and anomalous divergence
297 across the North American Monsoon and Central Plains regions actually oppose the OND
298 climatology. This may indicate a tendency in the model for GHG warming to extend the
299 JAS climatological pattern of transient eddy moisture convergence/divergence later in the
300 year. Alternatively, this pattern could reflect a poleward shift in the transient eddy field
301 during the fall across North America (Simpson et al. 2014).

302 In addition to the mean flow induced drying over the North American Monsoon region
303 during the cold season, precipitation during the summer shows an overall shift towards
304 delayed monsoon onset and withdrawal. This shift in monsoon seasonality has been docu-
305 mented previously in CMIP5 model simulations for global monsoon regions, including North

306 American (Cook and Seager 2013; Lee and Wang 2014; Seth et al. 2011, 2013). Drying
307 and warming in the winter and spring creates an enhanced convective barrier, suppressing
308 precipitation and delaying the monsoon onset. Once the monsoon becomes fully established,
309 however, the surface is warm and moist enough to overcome the increased stability constraint,
310 and precipitation increases.

311 **4. Impacts on water resources, ecosystems, and land-** 312 **scapes of future changes in seasonality**

313 The changes in seasonality identified here will have important consequences for fauna and
314 flora, ecological and riparian systems, water resources, and resource management efforts in
315 WNA. Climate change in WNA will likely diminish total water resources, with important
316 ramifications for agriculture, municipalities, and natural resource management (Hagemann
317 et al. 2013; Schewe et al. 2013; Seager and Vecchi 2010; Seager et al. 2013). But manage-
318 ment and adaptation initiatives to address these changes will also need to account for large
319 sub-annual redistributions and shifts in seasonality of the same water resources. Indeed,
320 there is evidence that these seasonal hydroclimate changes may already be occurring (e.g.,
321 Fritze et al. 2011; Pederson et al. 2011; Polley et al. 2013; Stewart et al. 2005). As they
322 unfold they will have significant impacts on the ecological and social systems in the region.
323 Of particular concern is the widespread decrease in spring runoff and the more general drop
324 in runoff in the Central Plains and monsoon region. These runoff changes will impact river
325 flows in the spring and summer with consequences for riparian ecosystems and the wildlife

326 that depend on them, including migratory birds (Perry et al. 2012).

327 Other impacts are also likely. Reductions in snowfall and a shift from snow to rain
328 will likely have negative impacts on winter tourism (e.g., skiing, snowboarding; Scott and
329 McBoyle 2007; Elsasser et al. 2002), and may even depress residential property prices and
330 employment in areas reliant on this seasonal income (Butsic et al. 2011). Combined with
331 increased evapotranspiration rates in the spring, these snowfall changes are also expected
332 to shift runoff from spring to winter. Critically, this runoff is important for refilling reser-
333 voirs that provide water for agricultural and municipal needs throughout the year. During
334 winter, however, reservoirs are often operated in flood protection mode, which means that
335 this earlier runoff may not be captured and stored for later use (Barnett et al. 2005; Fritze
336 et al. 2011). If reservoir management does not adapt and account for this change in runoff
337 seasonality, effective water availability will decline even if total annual runoff is the same.

338 North of Mexico, increases in evapotranspiration and declines in warm season precipita-
339 tion (spring and summer) are likely to have significant effects on important breeding and
340 migration habitats for a variety of species. The Northern Plains, for example, hosts the
341 Prairie Potholes wetlands, the primary breeding site for most of North America's duck pop-
342 ulations. The projected climate changes documented in this study, however, will act to dry
343 out these wetlands in summer and degrade this habitat, with expected negative impacts
344 on duck populations (Ballard et al. in press; Johnson et al. 2005). Such climatic shifts are
345 likely to affect other important hydroclimate-sensitive wildlife habitats as well, including the
346 Salton Sea in California (Cohn 2000; Kaiser 1999), the 'Sky Islands' of the Southwest (Coe
347 et al. 2012), and riparian habitats throughout WNA (Perry et al. 2012).

348 Fire activity in WNA is also expected to increase with climate change, and can be linked

349 to some of the projected seasonality changes. For example, wildfire activity and the length of
350 the fire season increases with earlier snow melt, as well as warmer temperatures and drought
351 (e.g., Marlon et al. 2012; Stephens et al. 2013; Westerling et al. 2006). In the North Amer-
352 ican Monsoon region the fire season usually ends with the first monsoon rains (Ray et al.
353 2007; Swetnam and Betancourt 1998); the projected delayed onset of the monsoon will thus
354 contribute to extending the fire season in this region.

355 Finally, seasonal hydroclimate shifts are also likely to have significant impacts on range-
356 lands and livestock production. Seasonal changes in moisture availability alter the com-
357 petitive landscape in grasslands, affecting plant community composition and competitive
358 interactions (Polley et al. 2013; Robertson et al. 2010). Within year variations in rangeland
359 productivity, and thus food availability for grazing species, is often tightly coupled with sea-
360 sonal variations in precipitation and evaporative demand (Polley et al. 2010). And changes
361 in precipitation seasonality may even have direct effects on livestock weight gain through
362 effects on forage quality (Craine et al. 2009, 2012). Given the shifts documented here, it
363 is expected that rangeland quality and livestock production will increase with warmer and
364 wetter conditions in the Northern Plains, while declining across the Southwest, Southern
365 and Central Plains, and even in the Northwest where summer season drought will inhibit
366 productivity (Polley et al. 2013).

367 **5. Conclusions**

368 The CMIP5 models reproduce the observed seasonality of precipitation and runoff across the
369 diverse climates of WNA, providing an opportunity to investigate seasonal scale hydrocli-

370 mate responses to greenhouse warming over the coming century. In aggregate, these models
371 point to an overall intensification of hydroclimate seasonality (wet seasons getting wetter
372 and dry seasons getting drier), and a shift in timing of runoff and precipitation. These large
373 seasonal trends are masked when analyzing annual average quantities, and can be attributed
374 to physical processes that vary across seasons and regions of WNA.

375 The largest and most consistent responses in the multi-model ensemble are a 1) con-
376 tinental scale warming in all seasons, 2) increased evapotranspiration from fall to spring
377 north of Mexico, 3) decreased winter and spring evapotranspiration in Mexico, and a 4) shift
378 from snow to rain during the cold season months. To first order, these changes are a di-
379 rect response to the greenhouse gas forced warming of the atmosphere. Projections of these
380 variables may thus be considered more robust relative to other variables for which there are
381 larger uncertainties and greater spread across ensemble members. Runoff decreases in the
382 spring and increases in the winter, a result of both increased evapotranspiration in the spring
383 and the shift in cold season precipitation from snow to rain.

384 Effectively addressing these challenges will require a number of strategies. Reservoir
385 management, for example, may be adjusted to better capture earlier runoff, at least up to a
386 point. Increases in fire frequency and severity, and resulting costs to forests and grasslands
387 and life and property, may be mitigated through proactive land management and planning.
388 Efforts to conserve landscapes, ecosystems and species will need to take careful account of
389 how shifts in seasonality will alter the environments and the likelihood for success of con-
390 servation efforts. Such decision-making will address much smaller spatial scales than we do
391 here. On the other hand the changes in seasonality identified here are large scale, coherent
392 and robust across models and, hence, these results could be used as a first-order guide for

393 adaptation strategies across many sectors.

594 List of Figures

- 595 1 Fraction of mean annual precipitation (1980–1999) falling within 3-month
596 seasons. Data from GPCP version 6 precipitation dataset (Schneider et al.
597 2014). Regions that serve as the focus of this study are outlined in the
598 dashed black lines: the Northwest Coast (127°W–118°W, 42°N–50°N), the
599 Southwest Coast (127°W–118°W, 33°N–42°N), the Montane West (118°W–
600 106°W, 35°N–45°N), the Northern Plains (114°W–96°W, 45°N–53°N), the
601 Central Plains (104°W–95°W, 30°N–45°N), and the North American Mon-
602 soon (112°W–102°W, 18°N–33°N). 37
- 603 2 Annual average changes in precipitation and total runoff (mm day⁻¹) in the
604 RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099
605 vs 1980–1999 (right column). Areas marked with **x** indicate regions where
606 changes in at least 18 of the 22 models (80%) agree with the sign of the
607 change in the multi-model mean. Small changes (< 5%) in the multi-model
608 mean are masked in gray. 38
- 609 3 Seasonally averaged multi-model mean surface air temperatures changes (K)
610 in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–
611 2099 vs 1980–1999 (right column). Areas marked with **x** indicate regions
612 where changes in at least 18 of the 22 models (80%) agree with the sign of
613 the change in the multi-model mean. 39

- 614 4 Seasonally averaged multi-model mean precipitation (rain and snow) changes
615 (mm day⁻¹) in the RCP8.5 projections: 2030–2049 vs 1980-1999 (left column)
616 and 2080–2099 vs 1980-1999 (right column). Areas marked with **x** indicate
617 regions where changes in at least 18 of the 22 models (80%) agree with the
618 sign of the change in the multi-model mean. Small changes in the multi-model
619 mean (< 5%) are masked out in gray. 40
- 620 5 Seasonally averaged multi-model mean snowfall changes (mm day⁻¹) in the
621 RCP8.5 projections: 2030–2049 vs 1980-1999 (left column) and 2080–2099
622 vs 1980-1999 (right column). Areas marked with **x** indicate regions where
623 changes in at least 18 of the 22 models (80%) agree with the sign of the
624 change in the multi-model mean. Small changes in the multi-model mean
625 (< 5%) are masked out in gray. 41
- 626 6 Seasonally averaged multi-model mean evapotranspiration changes (mm day⁻¹)
627 in the RCP8.5 projections: 2030–2049 vs 1980-1999 (left column) and 2080–
628 2099 vs 1980-1999 (right column). Areas marked with **x** indicate regions
629 where changes in at least 18 of the 22 models (80%) agree with the sign of
630 the change in the multi-model mean. Small changes in the multi-model mean
631 (< 5%) are masked out in gray. 42

- 632 7 Seasonally averaged multi-model mean runoff (surface and subsurface) changes
633 (mm day⁻¹) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column)
634 and 2080–2099 vs 1980–1999 (right column). Areas marked with **x** indicate
635 regions where changes in at least 18 of the 22 models (80%) agree with the
636 sign of the change in the multi-model mean. Small changes in the multi-model
637 mean (< 5%) are masked out in gray. 43
- 638 8 Model climatologies (1980–1999, historical scenario) for the Southwest and
639 Northwest coastal regions: precipitation, snowfall, evapotranspiration, and
640 runoff. Units for all variables are mm day⁻¹. Solid black line is the multi-
641 model mean, and the multi-model ensemble spread (+/-1 standard deviation)
642 is indicated by the gray shading. Blue line in the precipitation panels is the
643 observed climatology from the GPCC dataset, calculated for 1980–1999. 44
- 644 9 Monthly changes in precipitation, snowfall, evapotranspiration, and runoff for
645 the Southwest and Northwest coastal regions. Orange bars are the multi-
646 model mean difference for 2030–2049 minus 1980–1999; red bars are for 2080–
647 2099 minus 1980–1999. Whiskers indicate +/-1 standard deviation calculated
648 across the 22 member multi-model ensemble. 45
- 649 10 Model climatologies (1980–1999, historical scenario) for the Northern and
650 Central Plains regions: precipitation, snowfall, evapotranspiration, and runoff.
651 Units for all variables are mm day⁻¹. Solid black line is the multi-model mean,
652 and the multi-model ensemble spread (+/-1 standard deviation) is indicated
653 by the gray shading. Blue line in the precipitation panels is the observed
654 climatology from the GPCC dataset, calculated for 1980–1999. 46

- 655 11 Monthly changes in precipitation, snowfall, evapotranspiration, and runoff
656 for the Northern and Central plains. Orange bars are the multi-model mean
657 difference for 2030–2049 minus 1980–1999; red bars are for 2080–2099 minus
658 1980–1999. Whiskers indicate ± 1 standard deviation calculated across the
659 22 member multi-model ensemble. 47
- 660 12 Model climatologies (1980–1999, historical scenario) for the Montane West
661 and North American Monsoon regions: precipitation, snowfall, evapotranspi-
662 ration, and runoff. Units for all variables are mm day^{-1} . Solid black line is the
663 multi-model mean, and the multi-model ensemble spread (± 1 standard de-
664 viation) is indicated by the gray shading. Blue line in the precipitation panels
665 is the observed climatology from the GPCC dataset, calculated for 1980–1999. 48
- 666 13 Monthly changes in precipitation, snowfall, evapotranspiration, and runoff for
667 the Montane West and North American Monsoon regions. Orange bars are
668 the multi-model mean difference for 2030–2049 minus 1980–1999; red bars are
669 for 2080–2099 minus 1980–1999. Whiskers indicate ± 1 standard deviation
670 calculated across the 22 member multi-model ensemble. 49
- 671 14 Multi-model (17 models) mean climatology of seasonal moisture convergence
672 (historical simulation, 1980–1999): mean flow (left column) and transient
673 eddies (right column). Units are in mm day^{-1} . 50

674 15 Multi-model (17 models) mean changes in seasonal moisture convergence
675 (2080–2099 minus 1980–1999) from changes in the mean flow (left column)
676 and transient eddies (right column). Units are in mm day^{-1} . Stippled areas
677 indicate regions where changes in 13 of these 17 models agree with the sign
678 of the change in the multi-model mean.

51

Precipitation Seasonality

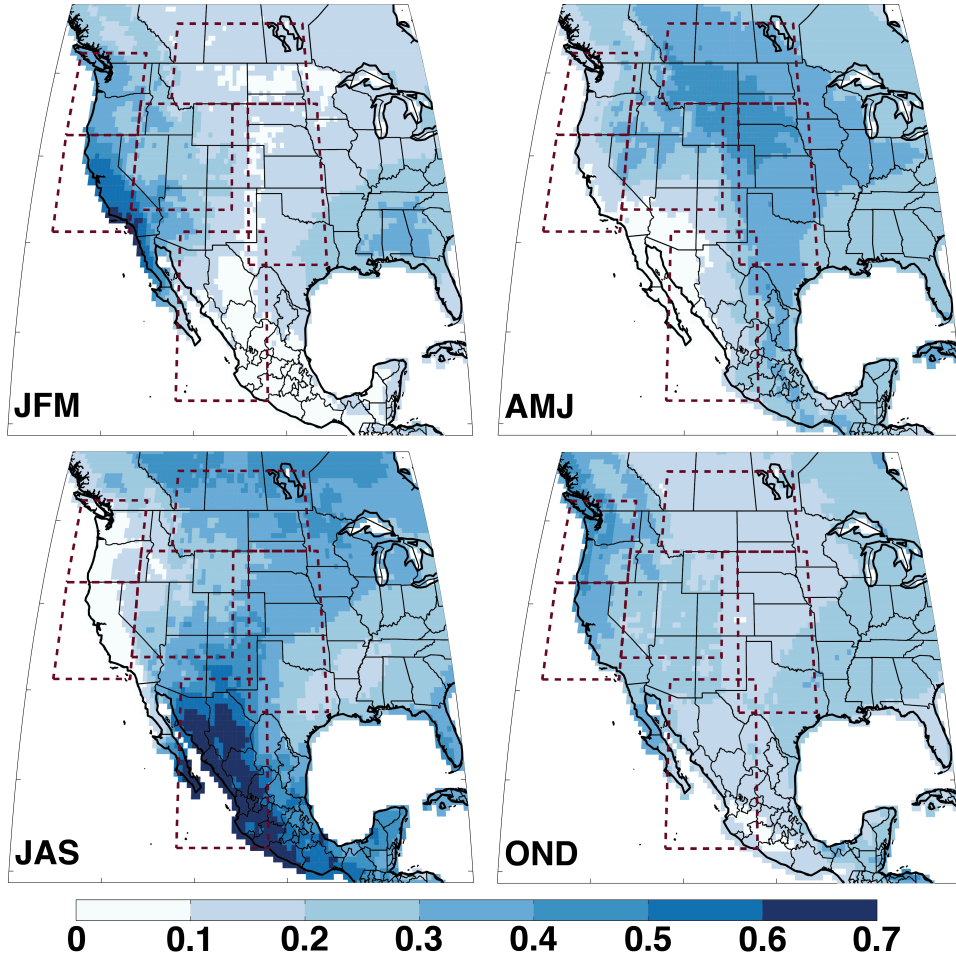

FIG. 1. Fraction of mean annual precipitation (1980–1999) falling within 3-month seasons. Data from GPCP version 6 precipitation dataset (Schneider et al. 2014). Regions that serve as the focus of this study are outlined in the dashed black lines: the Northwest Coast (127°W – 118°W , 42°N – 50°N), the Southwest Coast (127°W – 118°W , 33°N – 42°N), the Montane West (118°W – 106°W , 35°N – 45°N), the Northern Plains (114°W – 96°W , 45°N – 53°N), the Central Plains (104°W – 95°W , 30°N – 45°N), and the North American Monsoon (112°W – 102°W , 18°N – 33°N).

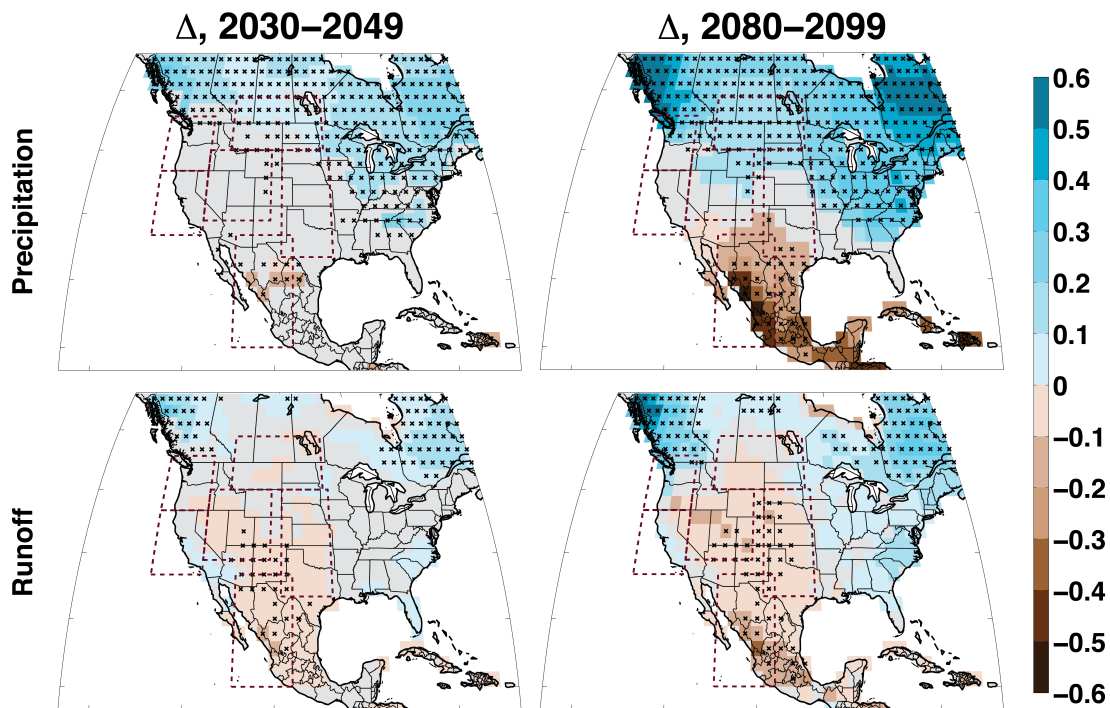

FIG. 2. Annual average changes in precipitation and total runoff (mm day^{-1}) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with x indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes ($< 5\%$) in the multi-model mean are masked in gray.

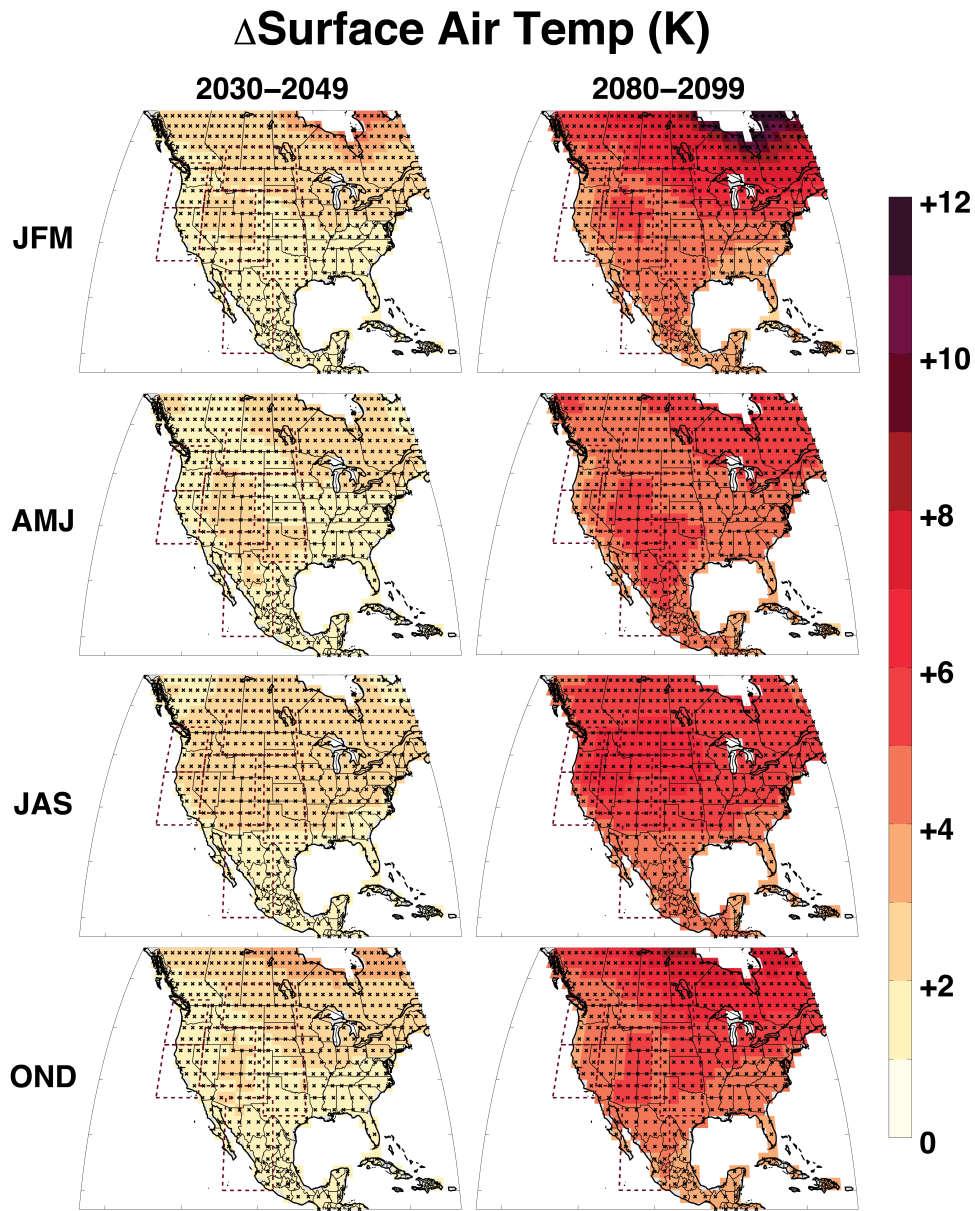

FIG. 3. Seasonally averaged multi-model mean surface air temperatures changes (K) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with x indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean.

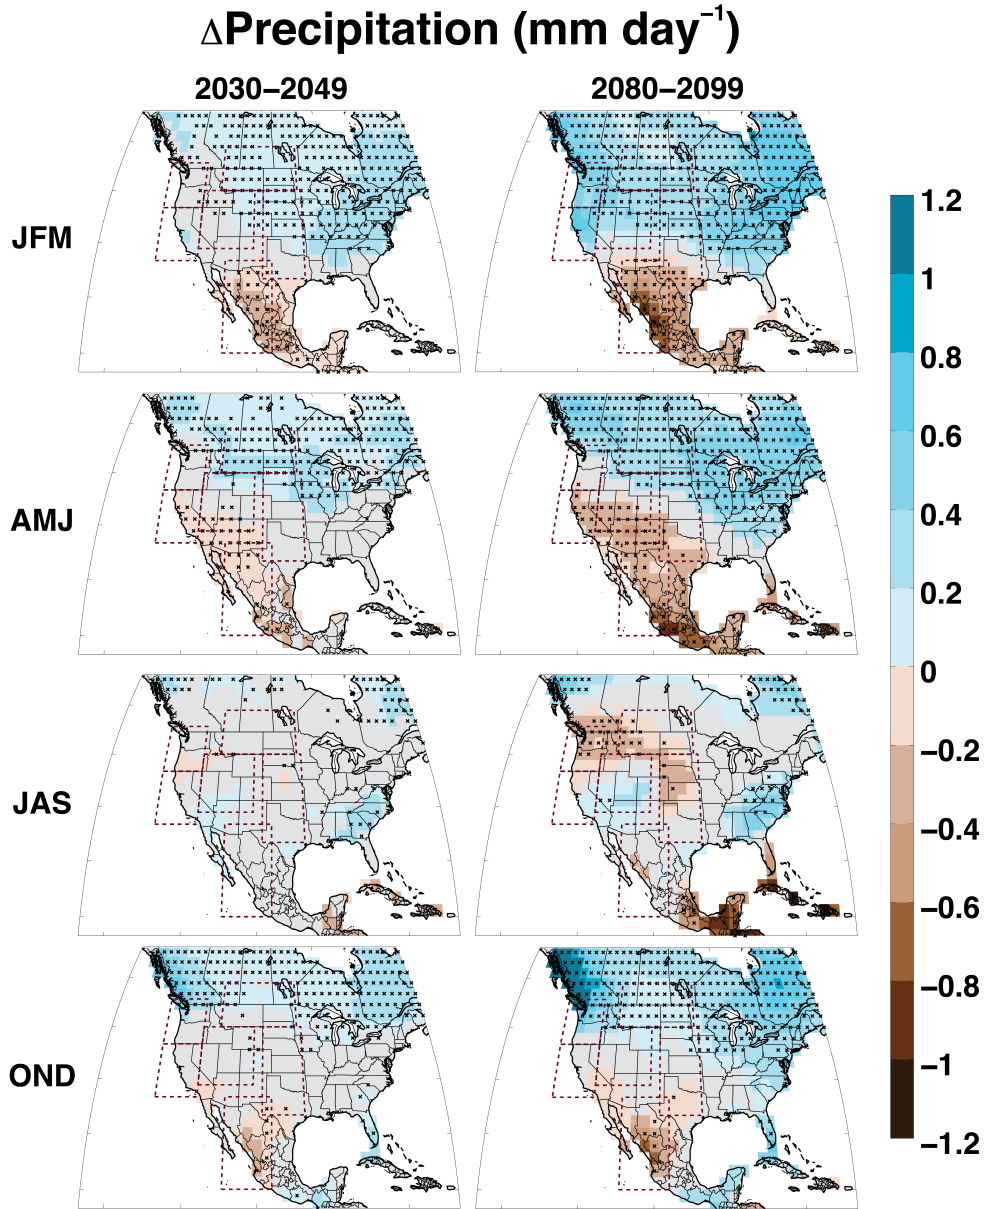

FIG. 4. Seasonally averaged multi-model mean precipitation (rain and snow) changes (mm day^{-1}) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with **x** indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes in the multi-model mean ($< 5\%$) are masked out in gray.

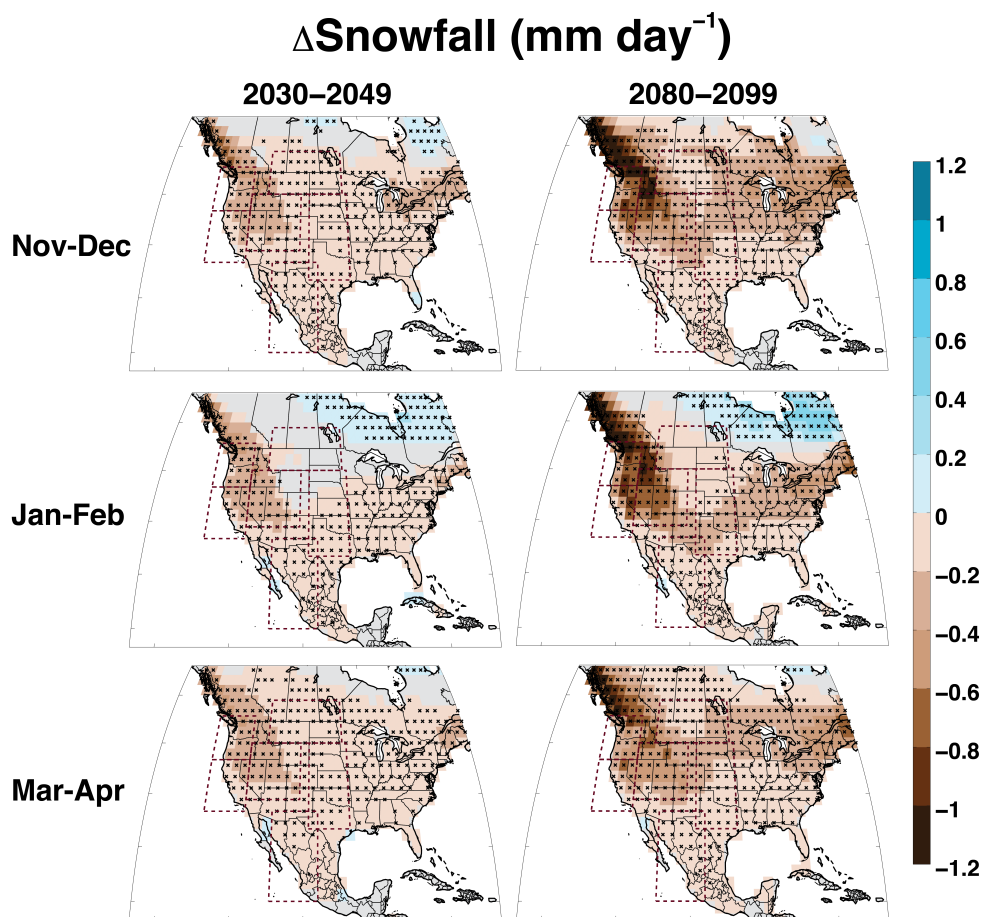

FIG. 5. Seasonally averaged multi-model mean snowfall changes (mm day⁻¹) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with x indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes in the multi-model mean (< 5%) are masked out in gray.

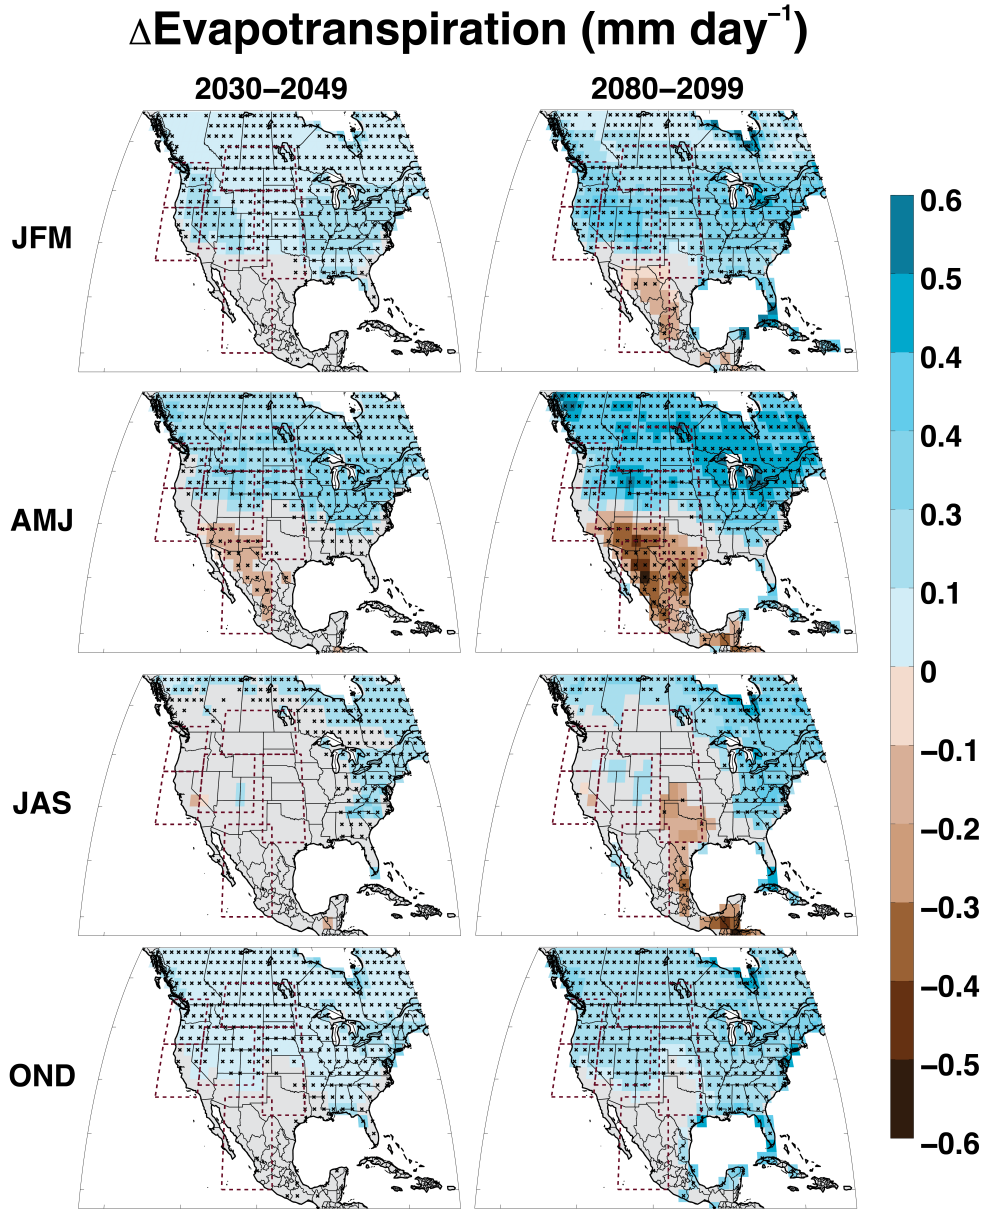

FIG. 6. Seasonally averaged multi-model mean evapotranspiration changes (mm day^{-1}) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with x indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes in the multi-model mean ($< 5\%$) are masked out in gray.

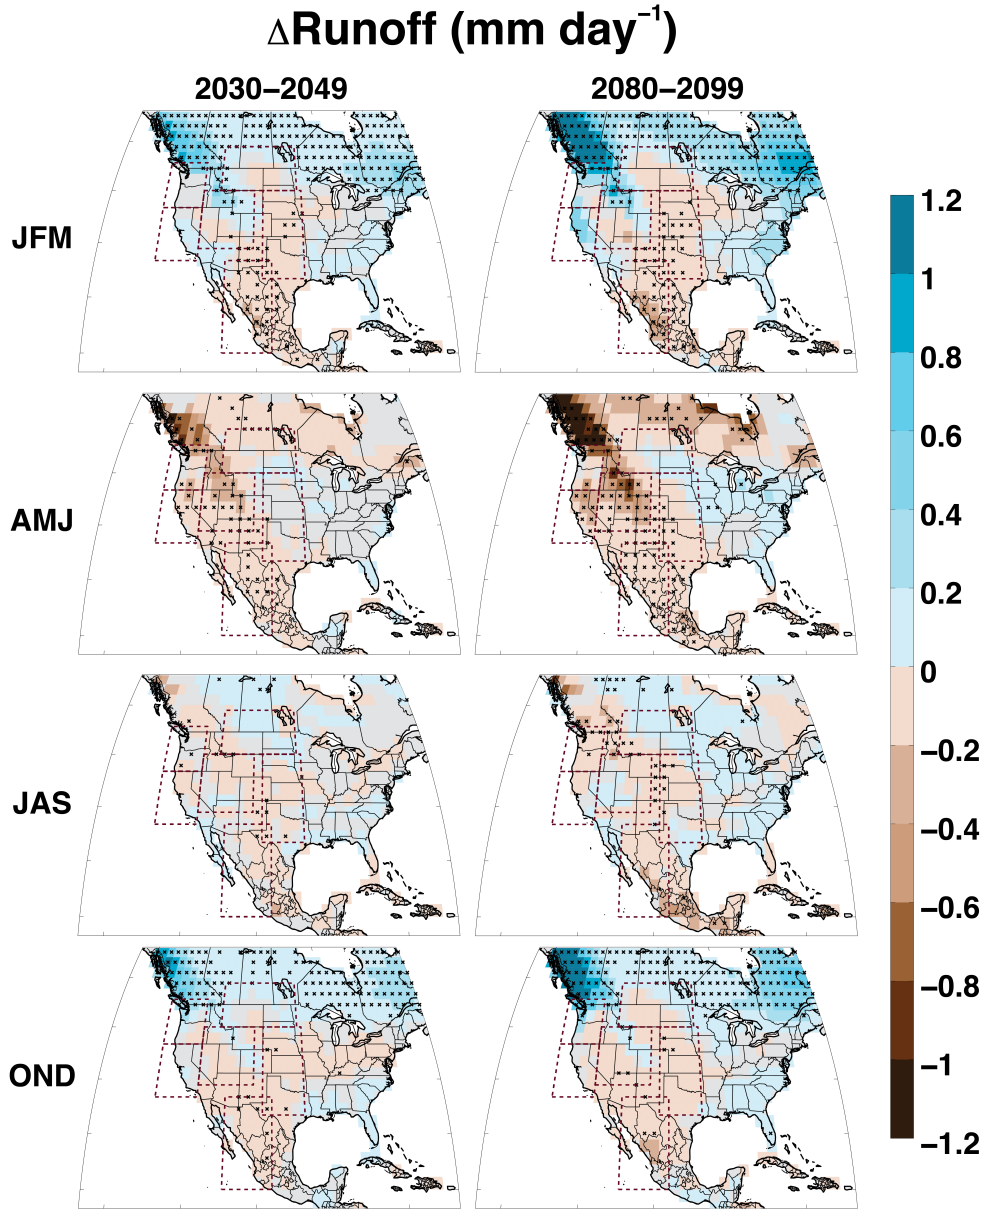

FIG. 7. Seasonally averaged multi-model mean runoff (surface and subsurface) changes (mm day⁻¹) in the RCP8.5 projections: 2030–2049 vs 1980–1999 (left column) and 2080–2099 vs 1980–1999 (right column). Areas marked with **x** indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes in the multi-model mean (< 5%) are masked out in gray.

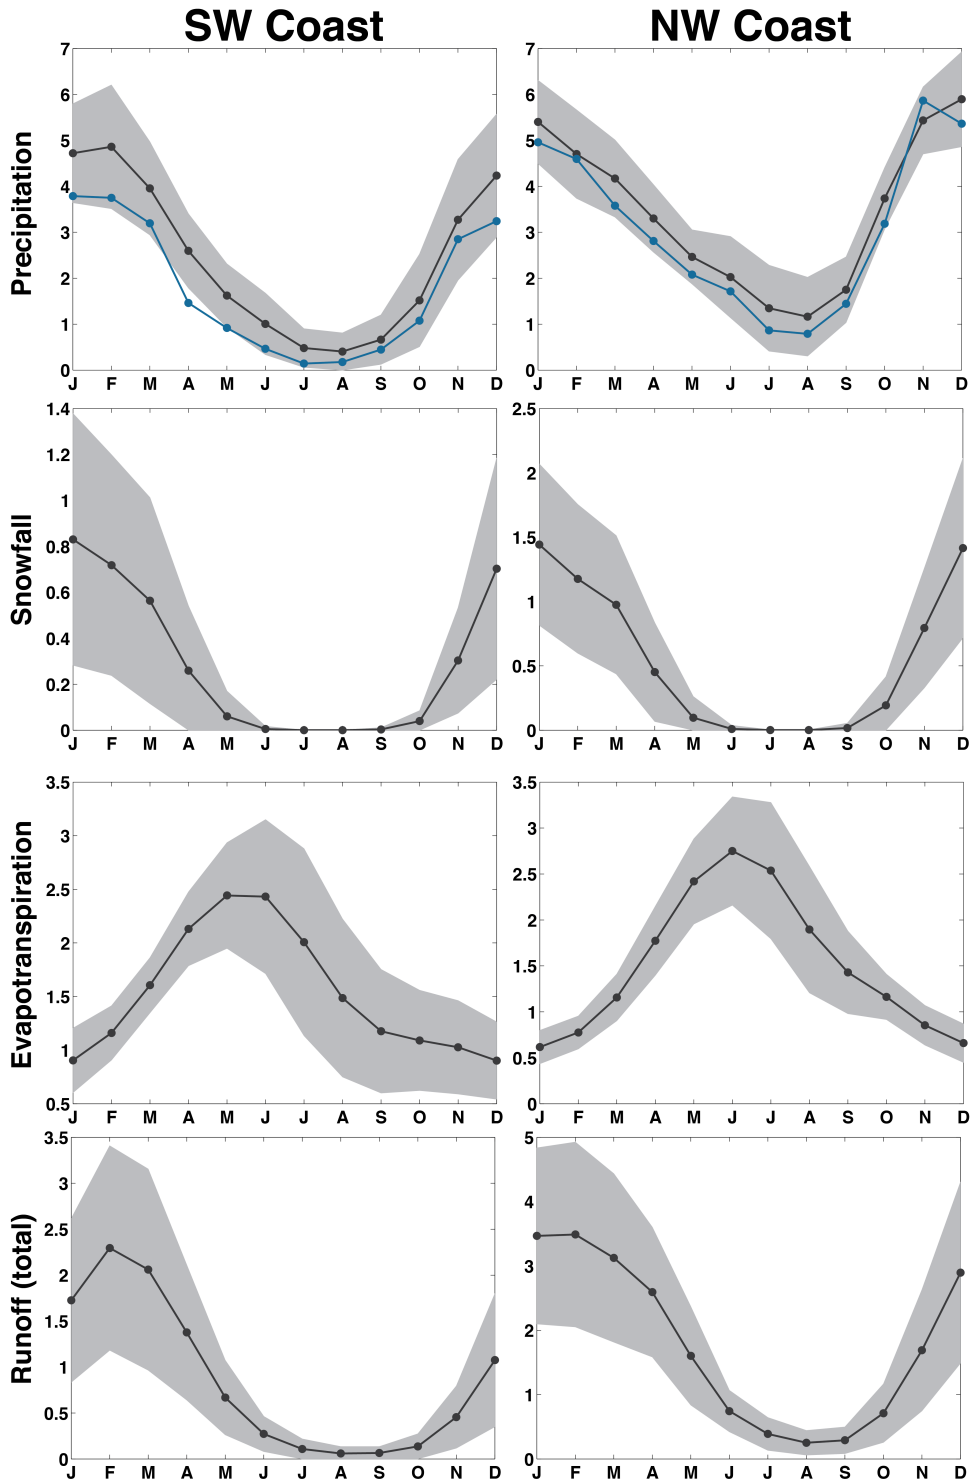

FIG. 8. Model climatologies (1980–1999, historical scenario) for the Southwest and Northwest coastal regions: precipitation, snowfall, evapotranspiration, and runoff. Units for all variables are mm day^{-1} . Solid black line is the multi-model mean, and the multi-model ensemble spread (± 1 standard deviation) is indicated by the gray shading. Blue line in the precipitation panels is the observed climatology from the GPCC dataset, calculated for 1980–1999.

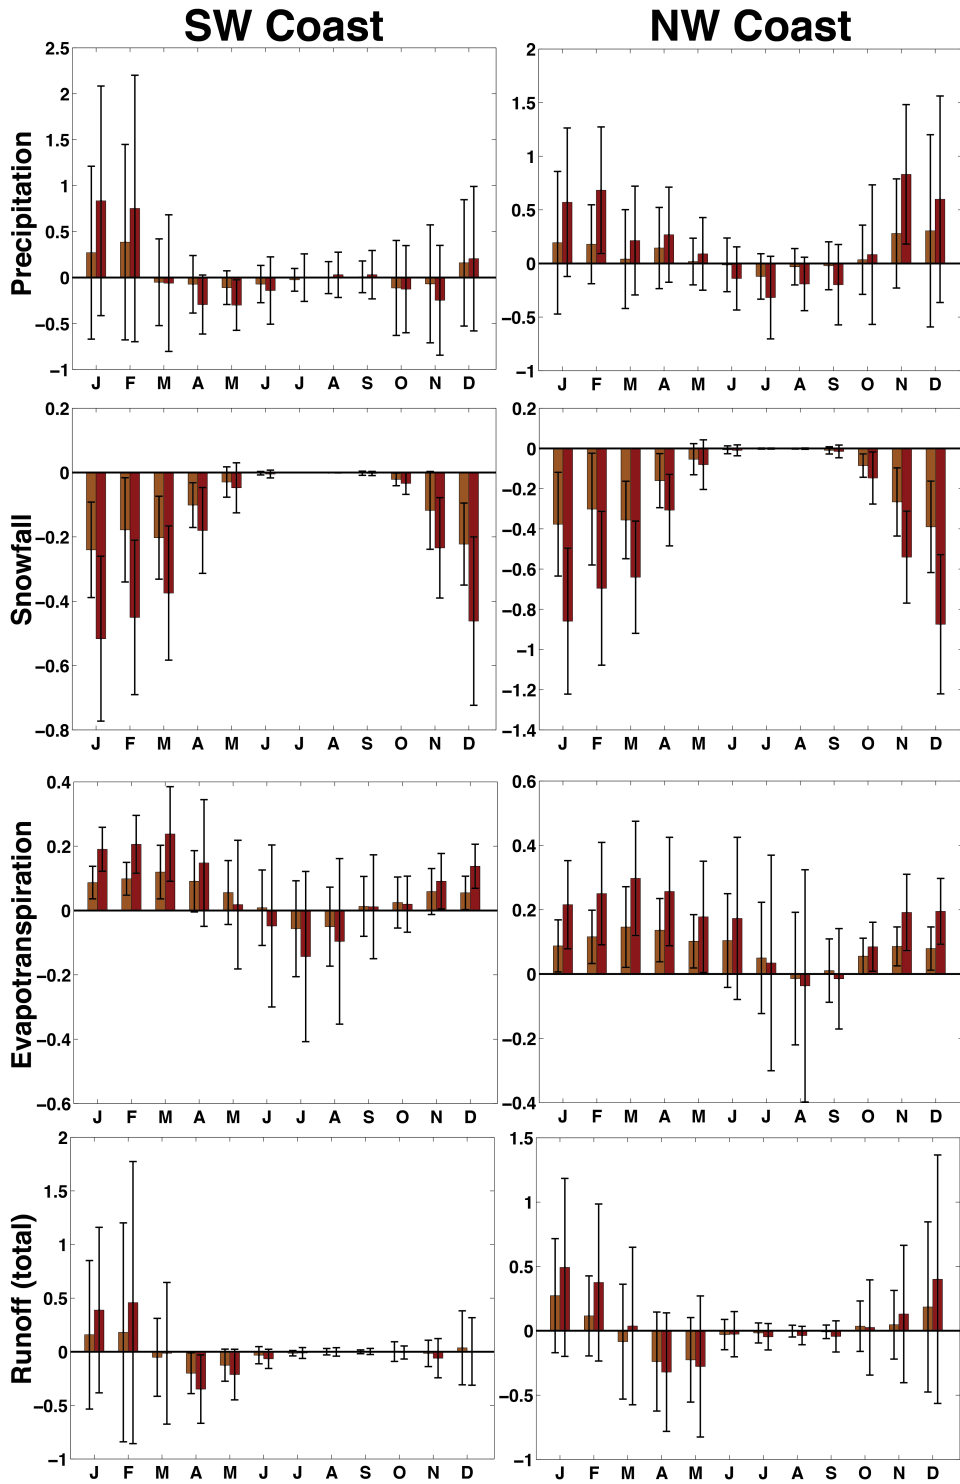

FIG. 9. Monthly changes in precipitation, snowfall, evapotranspiration, and runoff for the Southwest and Northwest coastal regions. Orange bars are the multi-model mean difference for 2030–2049 minus 1980–1999; red bars are for 2080–2099 minus 1980–1999. Whiskers indicate ± 1 standard deviation calculated across the 22 member multi-model ensemble.

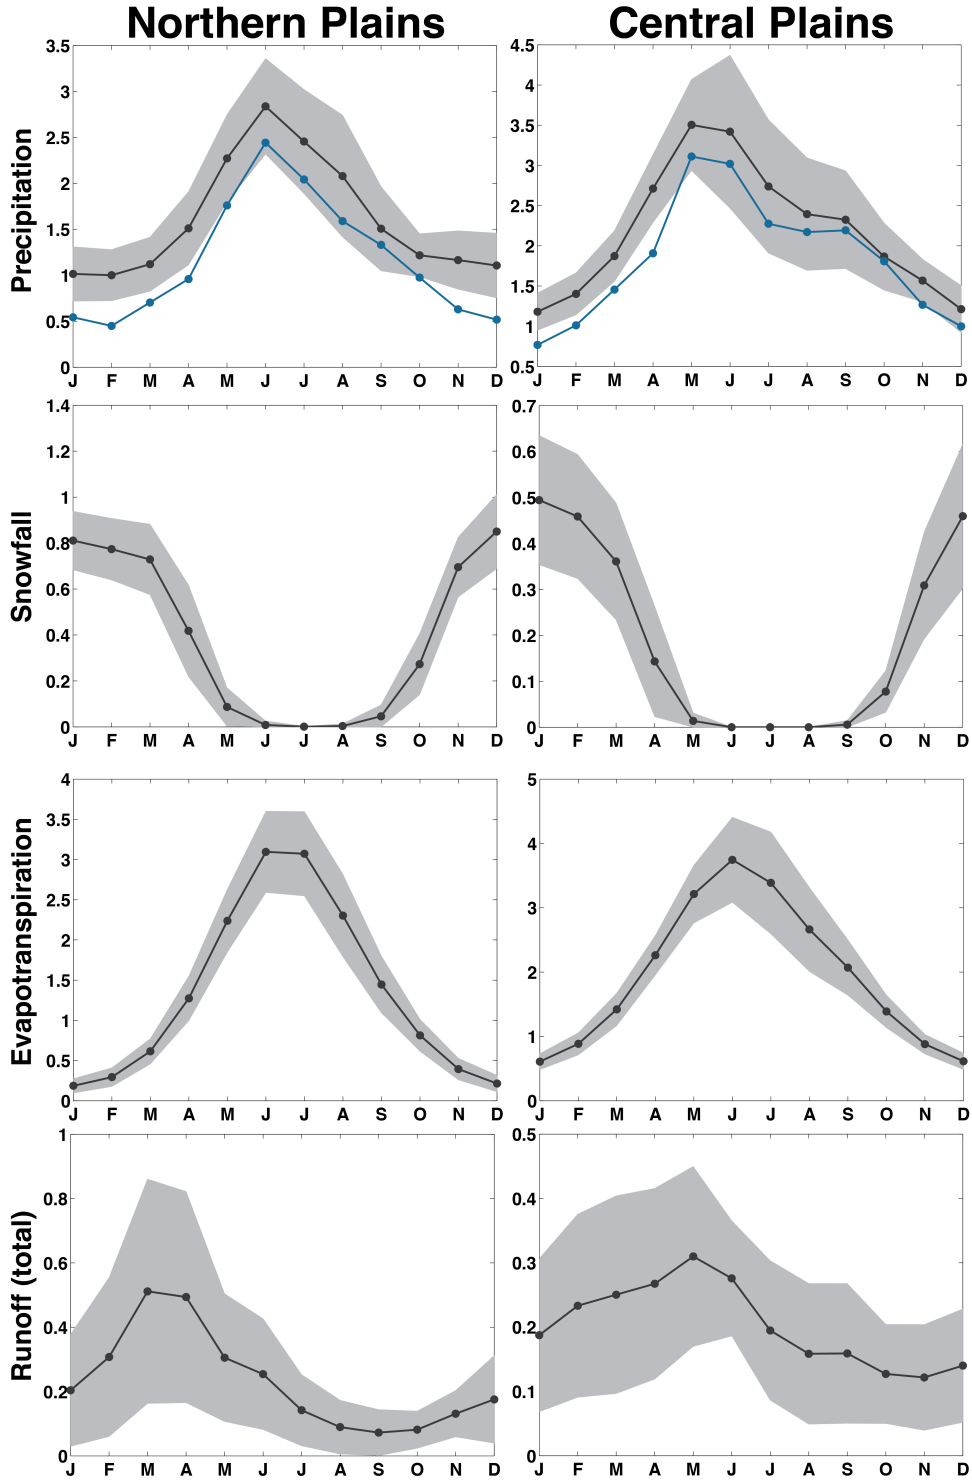

FIG. 10. Model climatologies (1980–1999, historical scenario) for the Northern and Central Plains regions: precipitation, snowfall, evapotranspiration, and runoff. Units for all variables are mm day⁻¹. Solid black line is the multi-model mean, and the multi-model ensemble spread (+/-1 standard deviation) is indicated by the gray shading. Blue line in the precipitation panels is the observed climatology from the GPCC dataset, calculated for 1980–1999.

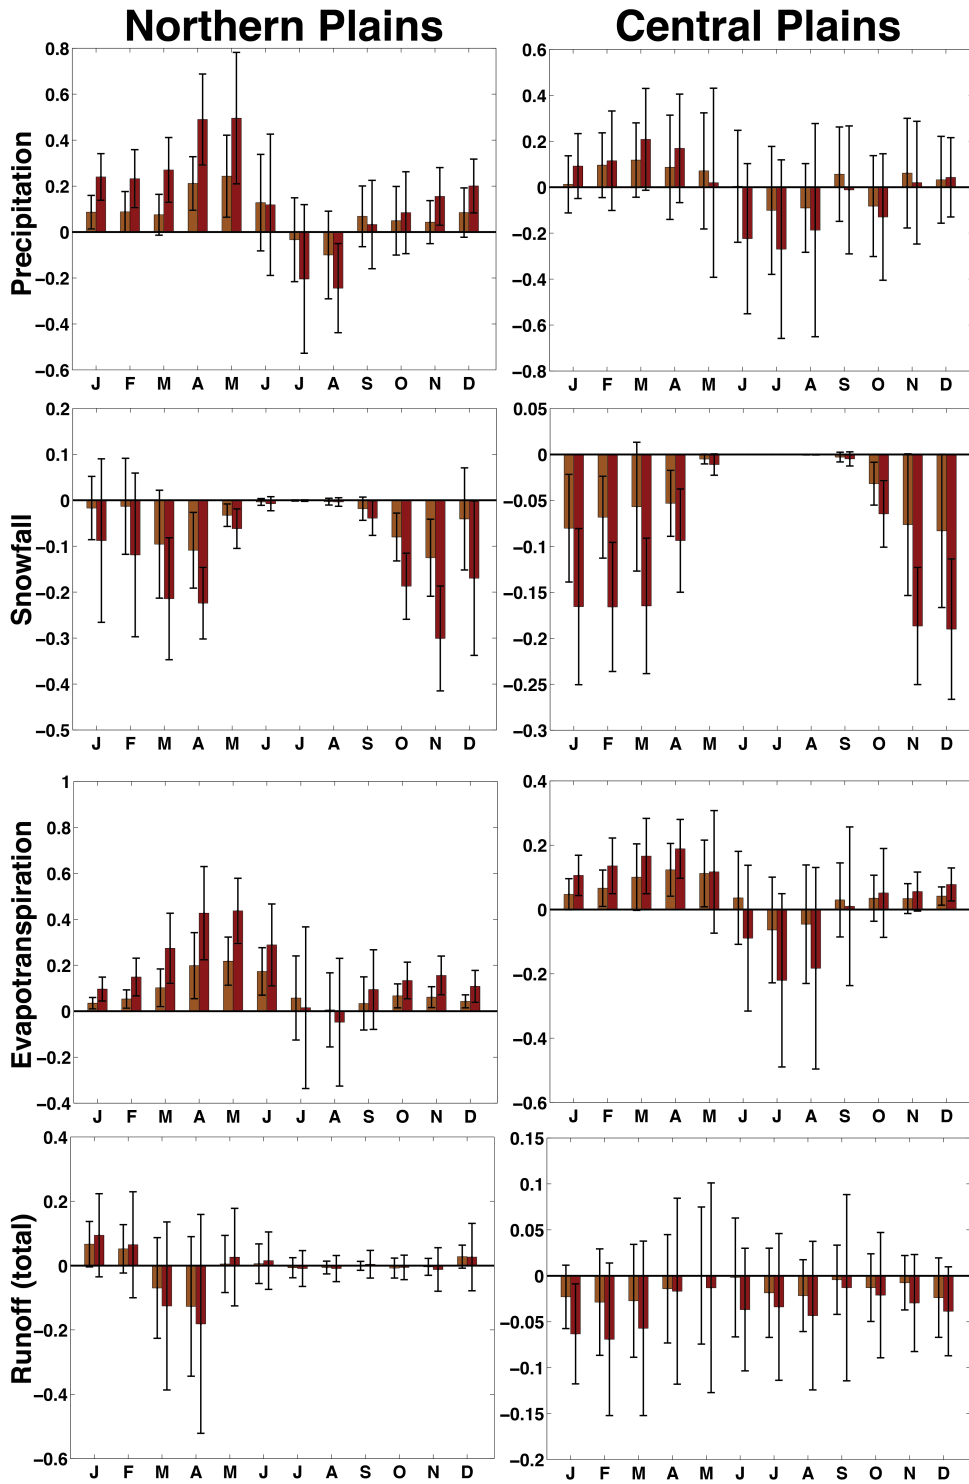

FIG. 11. Monthly changes in precipitation, snowfall, evapotranspiration, and runoff for the Northern and Central plains. Orange bars are the multi-model mean difference for 2030–2049 minus 1980–1999; red bars are for 2080–2099 minus 1980–1999. Whiskers indicate ± 1 standard deviation calculated across the 22 member multi-model ensemble.

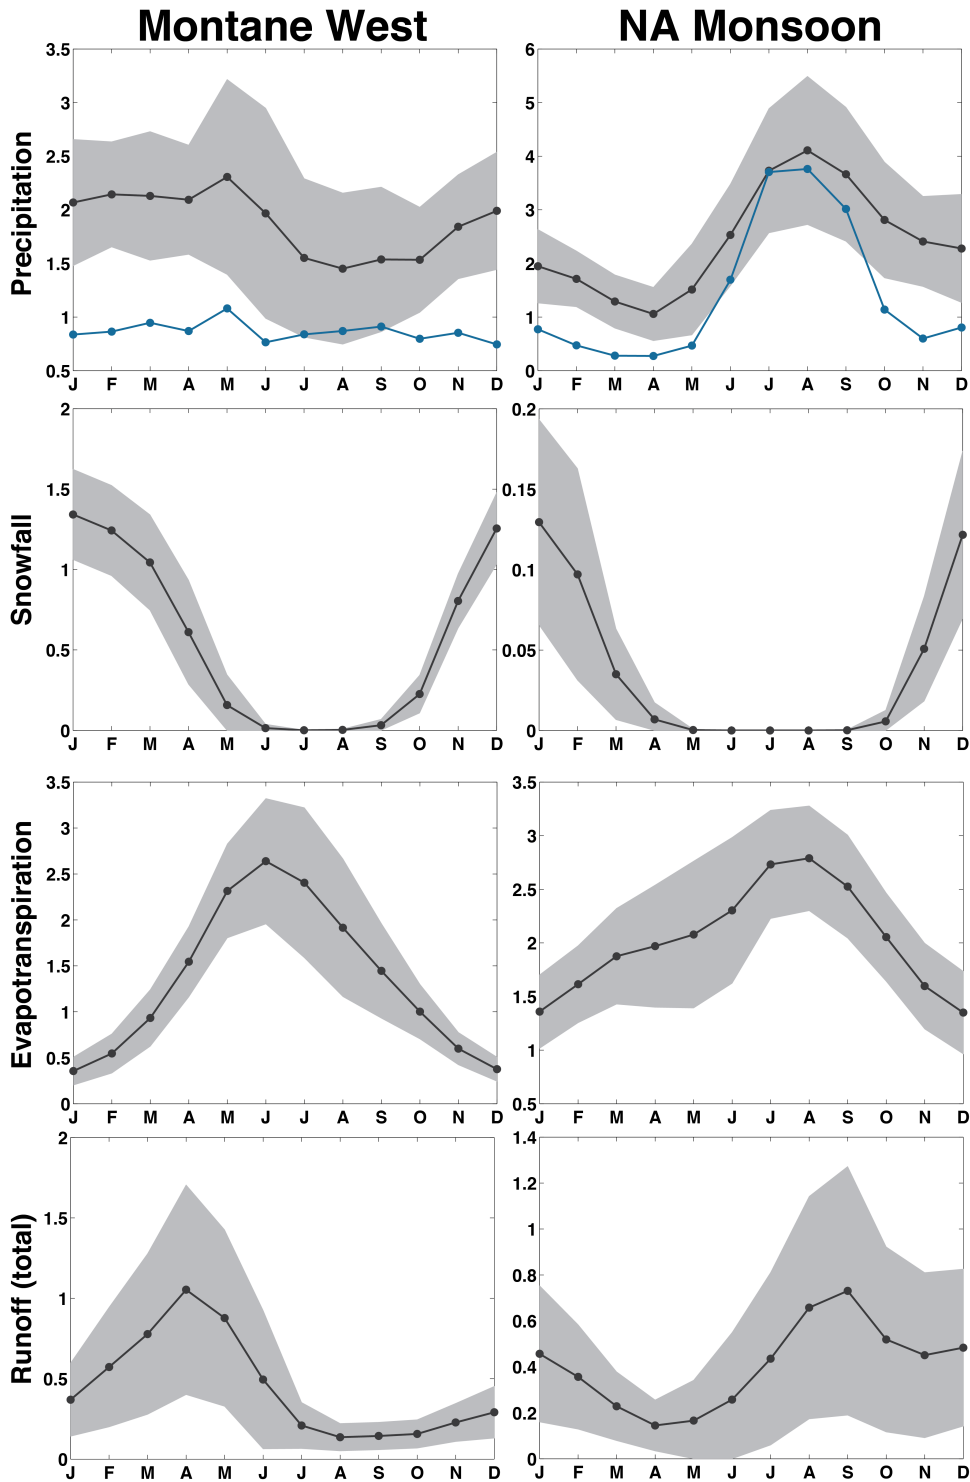

FIG. 12. Model climatologies (1980–1999, historical scenario) for the Montane West and North American Monsoon regions: precipitation, snowfall, evapotranspiration, and runoff. Units for all variables are mm day^{-1} . Solid black line is the multi-model mean, and the multi-model ensemble spread (± 1 standard deviation) is indicated by the gray shading. Blue line in the precipitation panels is the observed climatology from the GPCP dataset, calculated for 1980–1999.

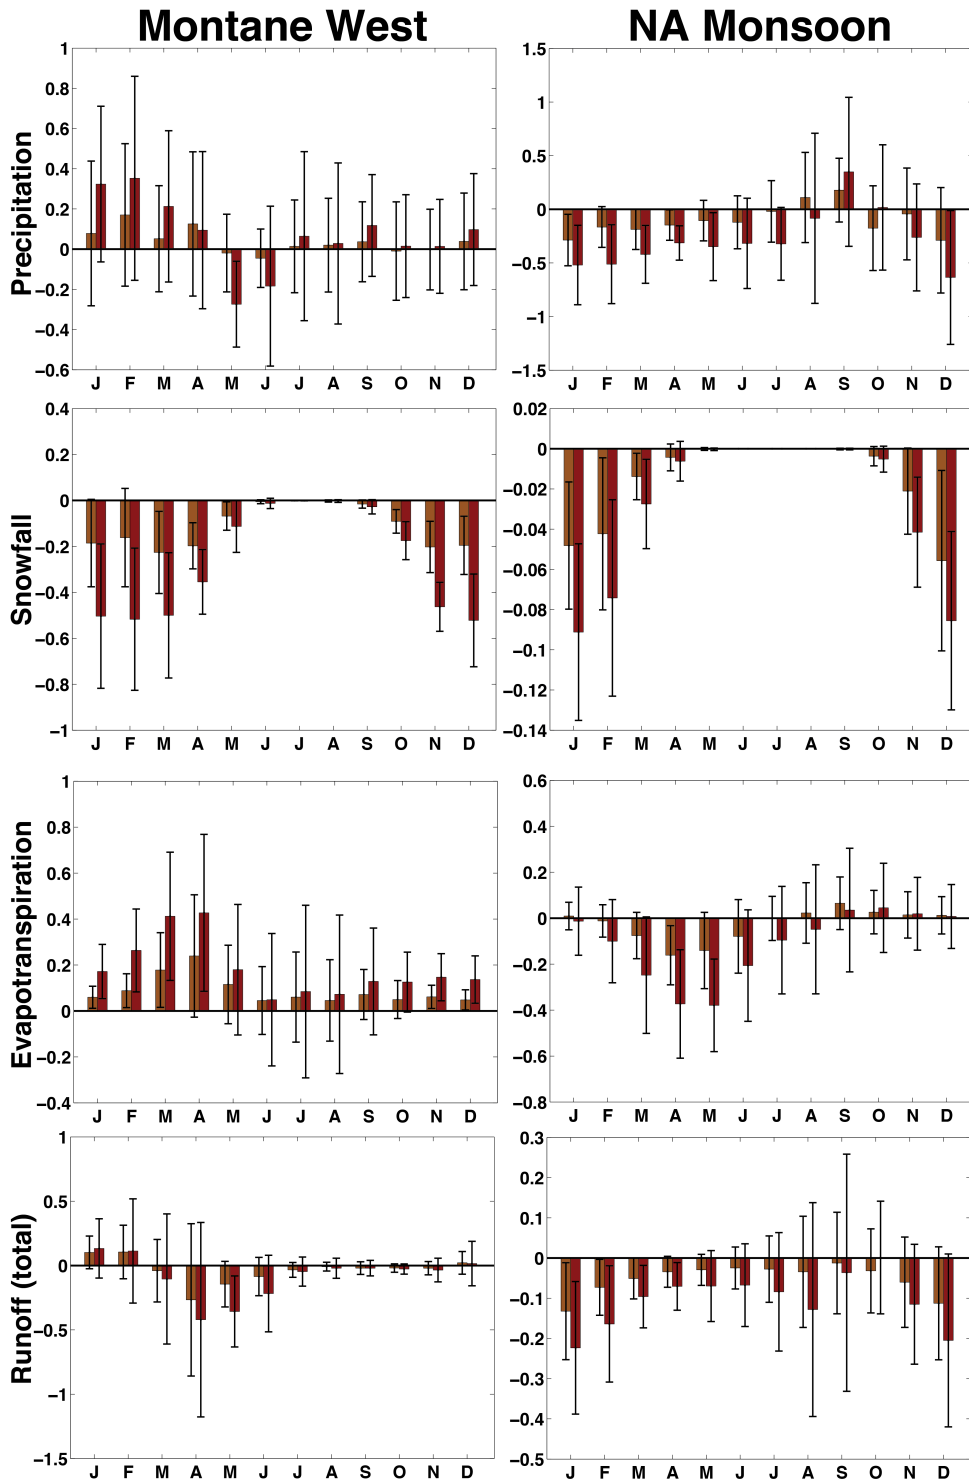

FIG. 13. Monthly changes in precipitation, snowfall, evapotranspiration, and runoff for the Montane West and North American Monsoon regions. Orange bars are the multi-model mean difference for 2030–2049 minus 1980–1999; red bars are for 2080–2099 minus 1980–1999. Whiskers indicate ± 1 standard deviation calculated across the 22 member multi-model ensemble.

Climatology, Moist. Conv. (1980-1999, mm day^{-1})

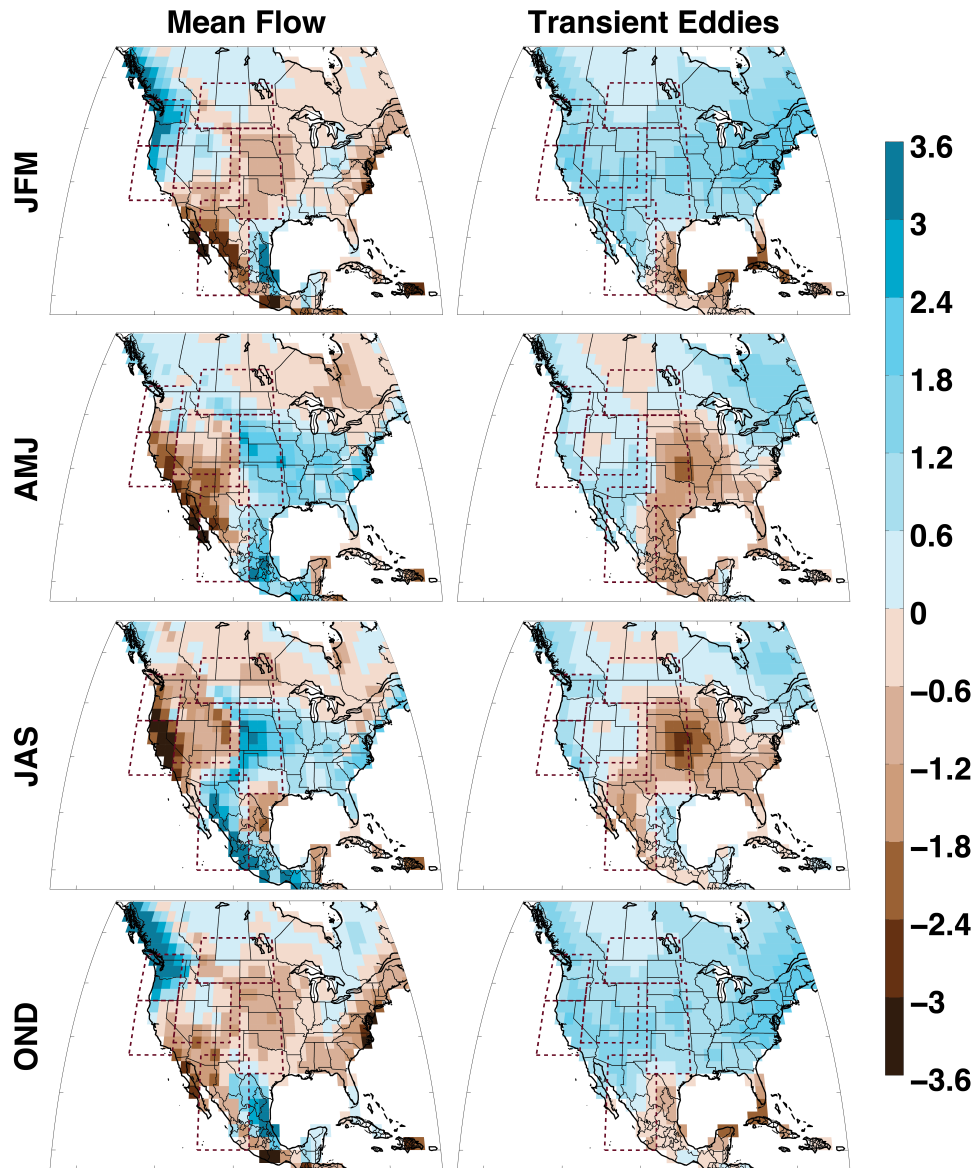

FIG. 14. Multi-model (17 models) mean climatology of seasonal moisture convergence (historical simulation, 1980-1999): mean flow (left column) and transient eddies (right column). Units are in mm day^{-1} .

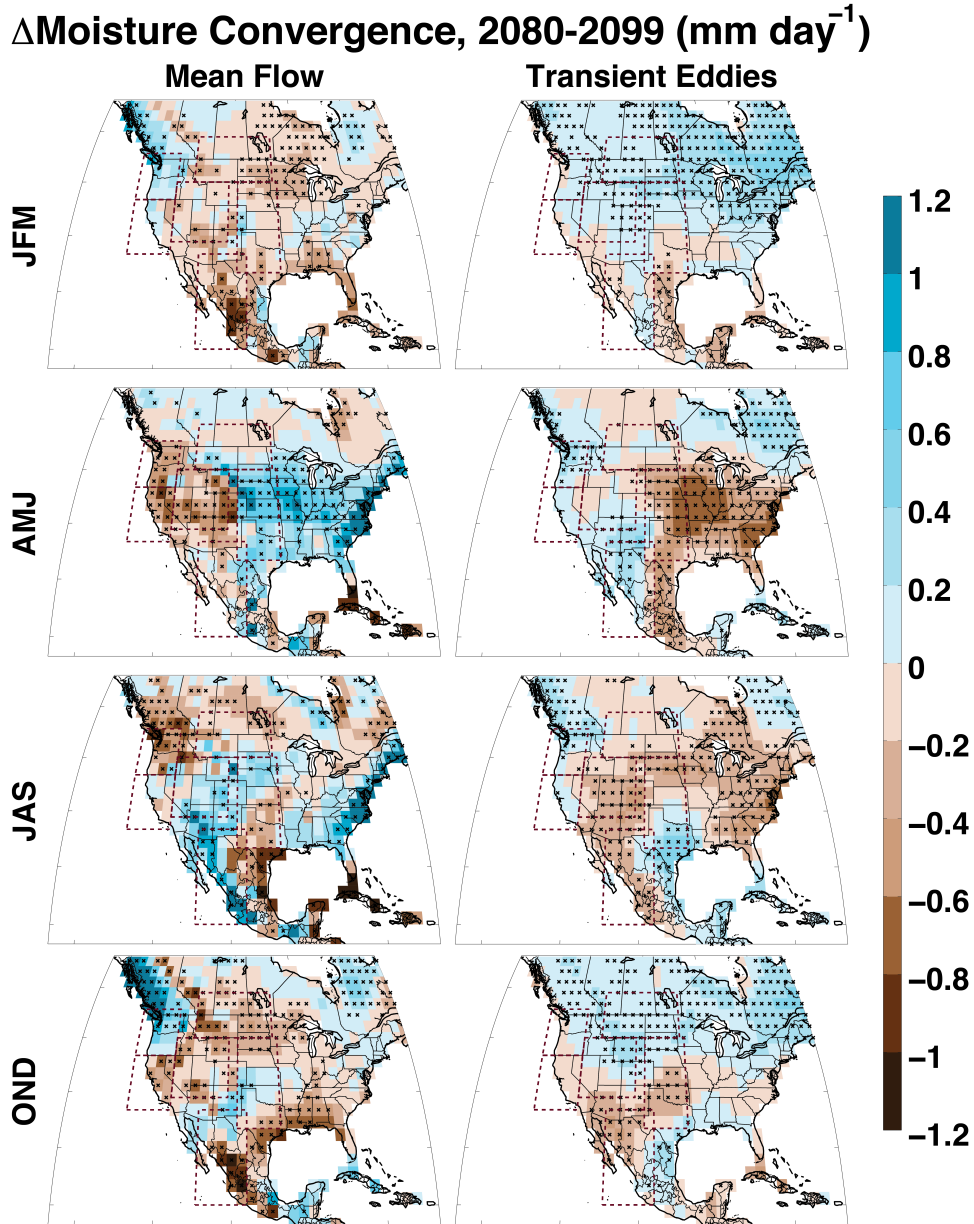

FIG. 15. Multi-model (17 models) mean changes in seasonal moisture convergence (2080–2099 minus 1980–1999) from changes in the mean flow (left column) and transient eddies (right column). Units are in mm day^{-1} . Areas marked with \times indicate regions where changes in at least 18 of the 22 models (80%) agree with the sign of the change in the multi-model mean. Small changes in the multi-model mean ($< 5\%$) are masked out in gray.
