Climate model projections suggest widespread drying in the Mediterranean Basin and wetting in Fennoscandia in the coming decades largely as a consequence of greenhouse gas forcing of climate. To place these and other “Old World” climate projections into historical perspective based on more complete estimates of natural hydroclimatic variability, we have developed the “Old World Drought Atlas” (OWDA), a set of year-to-year maps of tree-ring reconstructed summer wetness and dryness over Europe and the Mediterranean Basin during the Common Era. The OWDA matches historical accounts of severe drought and wetness with a spatial completeness not previously available. In addition, megadroughts reconstructed over north-central Europe in the 11th and mid-15th centuries reinforce other evidence from North America and Asia that droughts were more severe, extensive, and prolonged over Northern Hemisphere land areas before the 20th century, with an inadequate understanding of their causes. The OWDA provides new data to determine the causes of Old World drought and wetness and attribute past climate variability to forced and/or internal variability.

## INTRODUCTION

Instrumental observations show that the Mediterranean region has been drying since the 1970s (1). Coupled climate model simulations from Phase 5 of the Coupled Model Intercomparison Project archive, performed as part of the Intergovernmental Panel on Climate Change Working Group 1 Fifth Assessment Report (2), further suggest that the Mediterranean will undergo severe and widespread drying in the coming decades as a consequence of rising greenhouse gases (GHGs) (3). However, the recent drying trend has been variably attributed to a mixture of natural climate variability and anthropogenically forced change (4, 5), with similar challenges in understanding both wetting and drying trends in other parts of Europe and farther afield (6, 7). This uncertainty arises because the instrumental climate records used in attribution studies are relatively short, are likely to be confounded by unspecified levels of GHG forcing, and are unlikely to include the full range of natural variability. In addition, determining the complete range of possible future climate states from climate models requires knowing both the response to changes in anthropogenic forcing and the potential range of natural variability that will underlie it. Climate models are essential tools for diagnosing ongoing and future climate change, making it necessary to determine how well they represent each of these drivers of climate variability.

An extended record of natural hydroclimatic variability from tree-ring reconstructed drought and wetness before the instrumental era is a crucial estimate of past climate variability caused by both forced variability and internal variability, which is ideal for assessing the true range of hydroclimate variability in the preindustrial past and the degree to which climate models properly represent it. The North American Drought Atlas (NADA), released in 2004 (8), made clear that droughts of

a severity and a longevity not seen in the 19th and 20th centuries occurred more frequently in earlier centuries, and this has sparked a range of efforts to determine whether climate models can simulate such events (9, 10). Here, we present the Old World Drought Atlas (OWDA), a new tree ring-based field reconstruction of past droughts and pluvials over Europe, North Africa, and the Middle East spanning the Common Era (CE), which will facilitate similar advances in understanding and modeling hydroclimate variability in the Old World.

## RESULTS

The OWDA is a set of year-by-year maps of reconstructed summer season [June–July–August (JJA)] self-calibrating Palmer Drought Severity Index (scPDSI) (11) on a 5414-point half-degree longitude-by-latitude grid (Fig. 1). The JJA scPDSI reflects spring–summer soil moisture conditions and is the same season reconstructed in the NADA (8) and Monsoon Asia Drought Atlas (MADA) (12). The OWDA is based on the same regression-based climate field reconstruction method used to produce the NADA and the MADA. These common properties allow for direct comparisons of the drought atlases. The OWDA also provides a longer and more spatially complete reconstruction of hydroclimatic variability over the Old World compared to previous estimates based on instrumental, historical, and natural records (Supplementary Materials). In addition to the tree-ring data from living trees, we assembled an exceptional amount of historical, archaeological, and subfossil tree-ring data to extend many chronologies back a millen-

**Fig. 1. Map of the JJA scPDSI target field (small black grid points) and the 106 chronology tree-ring network used for reconstruction.** There are 5414 half-degree scPDSI grid points. The OWDA tree-ring network (filled triangles shaded by start year) illustrates the reasonably uniform coverage of chronologies across the domain, except for Russia.

nium or more in time (Supplementary Materials). This allows us to make informed statements about the properties of hydroclimatic variability during medieval times in the Old World.

Dendroclimatic reconstructions are traditionally validated through comparisons of tree ring-based climate estimates with 20th-century instrumental data that have not been used for calibration (8, 12). This was performed as well for the OWDA by withholding 1901–1928 instrumental scPDSI data from the 1928–1978 calibration period for validation testing (Supplementary Materials). However, the vast amount of historical climate information from Europe extending back many centuries (13) allows for far more extensive comparisons of OWDA reconstructions with recorded droughts and pluvials. We compare the OWDA to several historically documented extreme hydroclimatic events (with additional comparisons shown in Supplementary Materials), with emphasis on those events that reflect the spring–summer moisture conditions most relevant to the OWDA.

**The great drought of 1921:** On the basis of an evaluation of instrumental climate data not used to calibrate the OWDA, this drought was described as “a year of unprecedentedly small rainfall” over large parts of the British Isles, with the worst deficit occurring in southeastern England where London may have experienced its driest year since 1774 (14). The OWDA map for 1921 (Fig. 2A) shows the most extreme drought occurring in southern England, in accordance with the report. It also shows serious drought extending over most of central Europe but less dry conditions in peninsular Italy, a result consistent with other reports from Europe (15).

**The great drought of 1893:** Evaluated again using instrumental climate data, “... the absence of rain was phenomenal” during the period March to June, with a rainfall deficit gradient from 30 to 50% of normal over southern England to 50 to 90% of normal over Scotland and Ireland (16). The 1893 OWDA map (Fig. 2B) shows a similar north–south gradient of rainfall deficit over the British Isles and also shows the drought extending over continental Europe, as alluded to in this report.

**The Irish famine of 1740–1741:** This event has been attributed to unusually low winter and spring temperatures in 1740, resulting in crop failures and subsequent famine (17). The OWDA is not well suited for determining temperature anomalies because it primarily reflects warm season hydroclimate. However, climate field reconstructions of seasonal precipitation from documentary and early instrumental data (18) indicate that spring–summer rainfall over Ireland in 1741 was well below normal relative to the modern average. Drought over Ireland may therefore have contributed to the severity of the famine through its negative impact on food production in 1741. The OWDA map of 1741 (Fig. 2C) indicates severe drought over Ireland that also extended over England and Wales, consistent with previously reported record rainfall deficits (19).

**The great droughts of 1616 and 1540:** Droughts over Czech lands have been reconstructed from documentary records since 1090 CE, with five “outstanding drought events” (1540, 1590, 1616, 1718, and 1719) described (20). We highlight the 1616 and 1540 droughts here but note that all five outstanding drought events over Czech lands are well expressed in the OWDA (Supplementary Materials). The 1616 drought began in the spring and continued throughout the summer with “great heat, dried-up rivers” and a mark on a “hunger stone” on the Elbe River (20). Similar conditions also extended into Switzerland and Germany. The OWDA map of 1616 (Fig. 2D) indicates severe to extreme drought over central and eastern Europe, much the same as indicated on Czech documentary records. The 1540 drought has been described as a “worst-case” event in terms of both precipitation deficit and excessive warmth

**Fig. 2. OWDA maps of known years of hydroclimatic extremes. (A to F)** The maps are presented in reverse chronological order based on documentary climate records: from the best years recorded by instrumental climate records [1921 (A) and 1893 (B)] to the lesser known years [1741 (C), 1616 (D), 1540 (E), and 1315 (F)]. See the text for details and refer to Supplementary Materials for more examples of historical droughts from documentary records.

over central Europe relative to droughts that have occurred over the last century (21). The OWDA map for 1540 (Fig. 2E) shows the widespread occurrence of moderate to extreme droughts in central Europe, consistent with reports (18, 19), but not a worst-case event even among the examples shown here.

The great European famine of 1315–1317: This is one of the most famous historical catastrophes in late medieval European history, a famine caused by a multiyear period of excessive wetness that made food production nearly impossible (22). This pluvial actually began in 1314, but the following year was considered the most catastrophic year, when “... there was universal failure of crops in 1315 in most if not all lands of Europe from the Pyrenees to Slavic regions, from Scotland to Italy” (22). The 1315 OWDA map (Fig. 2F) corresponds well to this pattern of excessive wetness and crop failure and also shows the drier conditions in southern Italy, “... which escaped the great crisis that raged north of the Alps” (22). The OWDA now provides strong evidence for the hydroclimatic conditions over Europe that were responsible for this catastrophe and shows its yearly progression from 1314 to 1317 in full detail (Supplementary Materials).

The spatial and temporal details of the OWDA reconstructions are a marked improvement in our knowledge of changing moisture conditions across the Old World during the Common Era (Supplementary Materials). These few illustrations alone show that the OWDA now provides a new basis for the study of pre- and postindustrial hydroclimatic variabilities and their possible causes and consequences on

the Old World. The “Medieval Climate Anomaly” (MCA) (23) and “Little Ice Age” (LIA) (24) periods are particularly interesting, as well as controversial, because of uncertainty over their conditions relative to the modern period and the degree of spatial heterogeneity in preindustrial climate (25). While debate about the exact characteristics of temperature variability during the MCA and LIA continues, hydroclimatic conditions remain even more poorly quantified. The NADA made clear that the MCA period in North America experienced severe and prolonged “megadroughts” (26, 27), with additional paleoclimate evidence for elevated aridity documented elsewhere in the Northern Hemisphere (NH) (28). Across Europe, glaciers advanced during the LIA, testifying to a generally cooler climate (24), but the hydroclimate signatures of the MCA and LIA in the Old World have been poorly constrained. Here, we use the OWDA for the first detailed comparison of the spatial patterns of MCA and LIA hydroclimate across the Old World for the periods 1000–1200 and 1550–1750 CE, which fall within the generally accepted time spans of the MCA and LIA (23, 24). The specific period chosen here for the MCA is also one in which a megadrought was previously reconstructed to have occurred in southern Finland (29). The modern period is defined as 1850–2012. For each epoch, composite maps of reconstructed scPDSI (Fig. 3A) are shown for the full OWDA domain (upper maps) as well as for just the statistically significant ( $P < 0.01$ ) regions of wetness and dryness (lower maps). The MCA period analyzed here is significantly drier over a larger portion of continental north-central Europe and southern Scandinavia than either the LIA

**Fig. 3. Comparison of mean scPDSI fields in the OWDA during periods associated with the MCA, LIA, and modern period (MOD).** (A) The mean fields were calculated over the time intervals indicated, and the areas in those fields with significant mean anomalies of wetness or dryness ( $p < 0.01$ , two-tailed, corrected for lag  $-1$  autocorrelation) are indicated in the middle set of maps. The area of maximum dryness during the MCA period is indicated by the yellow rectangle in the lower MCA map. (B) Average of OWDA reconstructions from within this rectangle. It confirms the drier conditions during the MCA period and also shows the occurrence of an extraordinary megadrought in the mid-15th century. CL, confidence level.

**Fig. 4. The NHDA based on the OWDA, NADA, and MADA. (A)** The temperate latitude regions of drought atlases within the dashed boxes are emphasized for purposes of comparison because not all drought atlases have boreal (for example, MADA) or tropical (for example, OWDA) reconstructions. **(B)** The original annually resolved drought reconstructions in each region were averaged from 1000 to 1989 CE, transformed into standard normal deviates (Z scores), and low pass-filtered to emphasize variability that was >30 years in duration. The low pass-filtered average series were renormalized to eliminate any differential weighting by region and averaged to produce the NHDA records (not renormalized) shown in black.

or modern period, considerably adding to the previous report of an MCA megadrought in southern Finland (29), and it now more completely defines the spatial pattern and extent of dryness during that time. In contrast, the Romania and Ukraine regions of eastern Europe have more similar patterns of dryness, and northern Fennoscandia and Russia have more similar patterns of wetness, in all three epochs. Notably, the overall timing of MCA dryness in north-central Europe is consistent with that described for large areas of North America (26, 27) (see later discussion).

A summary of the history of drought and wetness since 870 CE in the core region of Old World MCA drought (Fig. 3A, yellow rectangle) is presented in Fig. 3B. The overall mean  $\pm 1\sigma$  error is  $-0.44 \pm 0.04$  scPDSI units from the expected mean of zero for the 1928–1978 calibration period, which reflects the general tendency for drier conditions in the preindustrial past. In contrast, the most recent period (1998–2012) has been anomalously wet ( $+0.97 \pm 0.24$ ). It is necessary to go back to 1721–1739 to find a wetter period of comparable duration ( $+1.55 \pm 0.24$ ). As a relative index of drought, scPDSI has a high degree of spatial comparability across a broad range of precipitation climatologies (30). This allows us to compare this drought to another reconstructed medieval megadrought occurring at around the same time in western North America

(26). The 1000–1200 CE megadrought over north-central Europe has a reconstructed mean of  $-0.72 \pm 0.10$  scPDSI units. By comparison, the worst megadrought in the California and Nevada regions of the NADA (26) lasted from 832 to 1074 CE ( $-0.84 \pm 0.09$ , calculated after adjusting the mean of the California/Nevada series to match that of the north-central Europe series over their 870–2005 common interval). Thus, in terms of relative dryness as modeled by the scPDSI, this MCA megadrought in the OWDA is comparable to one of the more exceptional MCA megadroughts in the NADA.

Besides the MCA, Fig. 3B also reveals the occurrence of a mid-15th-century megadrought in north-central Europe. The most intense drought phase lasted for 37 years from 1437 to 1473 CE ( $-1.84 \pm 0.20$ ), with only two isolated years of positive scPDSI. The timing of this megadrought is similar to that of the worst drought reconstructed to have occurred over the past 1000 years in the southeastern United States (27). This suggests the existence of some common hydroclimate forcing across the North Atlantic, perhaps related to Atlantic Ocean sea surface temperature variations and/or the North Atlantic Oscillation (31, 32). Finally, a third megadrought occurred from 1779 to 1827 ( $-1.34 \pm 0.16$ ). This period has a subperiod of “major long-duration drought” (33) from 1798 to 1808 ( $-1.89 \pm 0.38$ ) in England and Wales identified from early instrumental

and historical climate information. It is also the driest period within the longer epoch (1779–1827) of persistently drier-than-average conditions over north-central Europe. More generally, Fig. 3B reveals the existence of large-amplitude decadal to centennial hydroclimate variability over Europe and shows that, like North America, megadroughts in the Old World were not restricted to just the MCA period. In comparison, hydroclimate variability over the 20th century, although large, does not appear unprecedented in amplitude or trend. Isolating signals of recent GHG-induced hydroclimate change from this complex record of natural variability will be challenging.

## DISCUSSION

The OWDA greatly expands our understanding of the spatiotemporal history of droughts and pluvials in the Old World. It confirms the occurrence of an MCA megadrought in north-central Europe, first noted in southern Finland (29), which is similar in timing, duration, and relative intensity to that found in the NADA for the western United States (26). This finding significantly adds to the realization that NH droughts were more prolonged during the MCA compared to the 20th century, with little understanding as to why. In addition, the example maps illustrate its considerable relevance to studies of hydroclimate impact on Old World societies and cultures over the Common Era.

The OWDA is an important new advancement toward achieving a full and consistent spatial coverage of hydroclimatic variability across the NH land areas during the Common Era, one of the primary goals of Kaufman and the PAGES 2k Consortium (34). Figure 4 shows progress toward the completion of a “Northern Hemisphere Drought Atlas” (NHDA) for the temperate latitude regions of the OWDA, NADA, and MADA (Fig. 4A). This gives us an opportunity to compare hydroclimatic variability between continents on a hemispheric basis back to the MCA for the first time.

A first comparison, based on normalized averages of reconstructed droughts smoothed to emphasize >30-year time scales of variability (Fig. 4B), shows little commonality in the timing of wet and dry epochs between drought atlas regions at the continental scale over the past 1000 years (average  $r = 0.05$ ). However, there are several periods of distinct antiphasing between regions, especially between the NADA and the MADA, which nonetheless suggests some dynamical links between them. The NHDA average has also shown a long-term positive trend from drier to wetter conditions over the temperate latitudes of the NH since the MCA. The addition of the OWDA to the NADA and MADA thus allows for more complete investigations of atmosphere-ocean dynamical influences on the hemispheric patterns of hydroclimate variability over the Common Era. The use of multiple climate field reconstructions (spatially and fully data-independent) represented by the OWDA, NADA, and MADA should better constrain the modes of climate variability responsible and greatly improve our understanding of the causes of hydroclimatic variability at interannual to centennial time scales. Furthermore, completion of the OWDA, together with available simulations of the last millennium, now allows us to determine whether state-of-the-art climate models in the NH contain realistic hydroclimate variability at interannual to centennial time scales [see Smerdon *et al.* (35) for a North American example]. This knowledge is essential to assessing whether models can correctly represent the range of future hydroclimates, including wet and dry extremes, that combine forced change with continued natural variability.

## MATERIALS AND METHODS

The scPDSI data used for reconstruction (11) are based on gridded Climatic Research Unit Time Series (CRU TS) monthly temperature and precipitation data (36) updated to version CRU TS 3.21 and covering the period 1901–2012. We examined the changing density of precipitation stations available for interpolation onto the CRU TS 3.21 precipitation grid before 1950 and found it to be stable back in time over most of the OWDA domain (Supplementary Materials). The greatest exception was found in Turkey and the Middle East, where little local precipitation station data were available before 1930 for interpolation to the half-degree grid. This is not desirable for evaluating reconstruction skills in those regions over the 1901–1927 regression model validation period. However, it is unlikely to adversely affect the tree-ring reconstructions themselves because the 1928–1978 calibration period used to produce the reconstructions barely overlaps with the period of reduced local precipitation data coverage. The correlation decay length (CDL) of the scPDSI field was also evaluated and found to be ~800 km, on average, but with considerable latitudinal variability. This information was useful for objectively defining the search radius used to find tree-ring chronologies for reconstruction of past droughts (see later discussion and Supplementary Materials for details).

The tree-ring data used to produce the OWDA came from the International Tree-Ring Data Bank and from contributions by European dendrochronologists, including a large quantity from the dendroarchaeology community. Incorporating archaeological tree-ring data into the tree-ring network, after updating with modern tree-ring data from appropriate younger living trees (37), enabled the reconstructions to be extended back a millennium or more over most of the OWDA domain. The resulting tree-ring chronologies were developed for climate reconstruction using the newest “signal-free” methods of tree-ring standardization (38, 39), with emphasis on preserving long-term variability due to climate. Because of considerable variation in the segment lengths of the archaeological tree-ring series in each of those tree-ring data sets and the associated difficulty in preserving long-term climate variability because of “segment length curse” (40), a modified signal-free regional curve standardization (SF-RCS) (39) method was devised and used (see Supplementary Materials for a detailed description of how RCS was performed).

The climate field reconstruction method used to produce the OWDA is the point-by-point regression (PPR) method (41), with an extension of the procedure producing ensembles of climate reconstructions (12, 42). The OWDA reconstruction presented here is the mean of eight ensemble members, with each member being based on the weighting of each tree-ring chronology used in PPR by some power of its correlation with scPDSI (42). The initial search radius used by PPR to locate tree-ring chronologies for reconstructing scPDSI at each grid point was set to 1000 km, a small enlargement over the estimated CDL (800 km) of the instrumental scPDSI data to account for some of the irregular spacings of the tree-ring chronology network shown in Fig. 1.

A value-added outcome of PPR was the ability to evaluate the climate sensitivity of the tree-ring chronologies used for scPDSI reconstruction. This evaluation, performed through a simple correlation analysis, conclusively demonstrated the overall moisture sensitivity of the tree-ring chronologies over most of the OWDA domain, a result that is highly consistent with an independent evaluation of the climate response of tree-ring chronologies in Europe (43). At high elevations in central Europe and at high northern latitudes in Fennoscandia, the level of moisture sensitivity does diminish and is increasingly replaced by sensitivity

to growing-season temperatures. This change in climate sensitivity has also been described by Babst *et al.* (43). The successful reconstruction of droughts in Fennoscandia, using a mixture of moisture- and temperature-limited tree-ring records (44), indicates that this change in climate sensitivity is not a serious issue (refer to Supplementary Materials for details).

## SUPPLEMENTARY MATERIALS

Supplementary material for this article is available at <http://advances.sciencemag.org/cgi/content/full/1/10/e1500561/DC1>

Introduction

OWDA as a scientific advancement over previous work

Gridded monthly scPDSI target field

OWDA tree-ring network

Climate sensitivity of OWDA tree-ring chronologies

Validation of OWDA tree-ring climate response

Augmenting tree-ring chronologies with historical tree-ring data

Standardizing OWDA tree-ring data for climate reconstruction

Standardizing OWDA historical/modern tree-ring data

Estimating low- to medium-frequency variance retention

Point-by-point regression

Comparisons with Pauling spring-summer precipitation reconstructions

Additional validation tests of the OWDA

**Acknowledgments:** Reviews of earlier drafts of this paper by K. Anchukaitis, M. Cane, B. Cook, J. Smerdon, and A. P. Williams improved its quality and are greatly appreciated. **Funding:** We thank the National Oceanic and Atmospheric Administration Climate Change Data and Detection Program for supporting this project (award NA10OAR4310123) and the National Science Foundation Earth System History Program (awards 0075956 and ESH0317288), ATM GEO/ATM Paleoclimate Program (award 0758486), and award 1103314 for additional long-term support in developing this research in the Mediterranean region. **Author contributions:** E.R.C. was fully responsible for data processing, statistical analysis, and production of the OWDA. G.v.d.S. provided the PDSI target field data. R.S. and Y.K. helped guide the development of the OWDA and worked on climate dynamics interpretation. W.T. and U.B. spearheaded the contribution of tree-ring data used in the OWDA. K.R.B., D.F., and P.J.K. contributed data and critically reviewed earlier drafts. The remaining coauthors contributed tree-ring data to the effort. **Competing interests:** The authors declare that they have no competing interests. **Data and materials availability:** All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. The OWDA reconstructions are archived with associated metadata ([www.ncdc.noaa.gov/data-access/paleoclimatology-data/datasets/climate-reconstruction](http://www.ncdc.noaa.gov/data-access/paleoclimatology-data/datasets/climate-reconstruction)) for routine public access and use. A second public access site will be set up at the International Research Institute for Climate and Society/Lamont-Doherty Earth Observatory Climate Data Library (<http://iridl.ldeo.columbia.edu>). The OWDA was made possible through the tree-ring data (most of them unpublished) provided by the dendrochronological community, which is engaged in various aspects of Old World tree-ring research. The availability of dendroarchaeological data from Europe enabled the OWDA to be extended back over most of the Common Era, which would have been impossible to do otherwise, and the newly available gridded scPDSI data from the Royal Netherlands Meteorological Institute (<http://climexp.knmi.nl>) provided the high-quality instrumental data for calibration. Other tree-ring data came from the International Tree-Ring Data Bank ([www.ncdc.noaa.gov/data-access/paleoclimatology-data/datasets/tree-ring](http://www.ncdc.noaa.gov/data-access/paleoclimatology-data/datasets/tree-ring)), from A. Billamboz (Dendrolab Archaeological Service, Baden-Württemberg, Germany), and from the archived tree-ring data contributed by K. Tyers and I. Tyers to the ADVANCE-10K project (<http://hol.sagepub.com/content/12/6/639.abstract>). Additional data related to this paper may be requested from the authors. Lamont-Doherty Earth Observatory contribution number 7938.
