ABSTRACT
Downscaled rainfall projections from 21 climate models from the CMIP5 archive are used to estimate future changes in rainfall erosivity in the continental United States. To estimate erosivity from rainfall in the absence of sub-hourly data, we have used both daily rainfall values and the modified Fournier index—which is based on monthly rainfall accumulation—and derived the scaling relationship between rainfall and erosivity from observational estimates of both.

The expectation of overall increase in erosivity is confirmed by these calculations, but a quantitative assessment is marred by large uncertainties. Specifically, the uncertainty in the method of estimation of erosivity is more consequential than that deriving from the spread in climate simulations, and leads to changes of uncertain sign in parts of the Southwest and Texas.

We suggest that progress can be made by establishing a more reliable functional relationship between daily rainfall and erosivity.

1. Introduction

Soil erosion has significant consequences for the productivity of land and the health of the riverine systems that receive the erosion materials. In an eroded soil, nutrients are lost, the effective root depth decreases, and runoff increases. In rivers, suspended sediments increase turbidity and transport pollutants, reducing the health of algae and fish and degrading the quality of drinking water, while excess sediments affect spawning fish, lower reservoir storage, and interfere with navigation. Erosion by water already causes about 55% of total global erosion (Bridges and Oldeman, 1999) threatening sustainability and the productive capacity of agriculture (Yang et al., 2003). A knowledgeable forecast of how erosion will change in the coming decades is thus necessary to plan for land stewardship and ecosystem preservation and it is made more urgent and complex by the general expectation that increases in rainfall intensity under global warming (Trenberth et al. 2003) will exacerbate erosion. There is widespread agreement (Soil and Water Conservation Soc-
ciety, 2003) on an increased risk of soil erosion under climate change, but the potential damage needs to be assessed against other drivers such as land cover (e.g., Nearing et al. 2005), and with better understanding of the uncertainty due to climate scenarios, spread in the climate projections, and methods of translating large scale climate anomalies into forcings for erosion models (e.g. Mullan et al. 2012; Zhang 2007; Zhang et al. 2011).

The forces that affect erosion are summarized in a widely used formula (the Universal Soil Loss Equation, USLE) and its derivates (RUSLE1 and RUSLE2) that were developed by the US Dept. of Agriculture. The USLE was developed for cropland in the early 1960s (Wischmeier and Smith 1965) and was later extended to other land uses (Wischmeier and Smith 1978, Dissmeyer and Foster 1980). Between the mid 1990s and the early 2000s, RUSLE1 and RUSLE2 expanded on the index based, empirically-derived USLE by use of hybrid models that add process-based equations, making these rules land-use independent and able to compute deposition. The empirical relationship at the basis of USLE describes soil loss as proportional to an erosivity factor (R, which describes the compound effects of the rainfall events that cause erosion), a soil erodibility factor (K, which takes into account the soil composition), a topographic factor (LS, basically the slope of the terrain), and two other quantities that describe the effect of vegetation, land use, and land management (C, the cover-management factor, and P, the support practices factor).

While climate, vegetation, and soils can all be coupled in complex ways (for example, excessive heat and drought can kill the vegetation cover and induce more soil loss, even if rainfall erosivity declines; see Nearing et al. 2004), we can start to address the role of climate change on soil erosion by first isolating the changes in the erosivity of rainfall while setting aside the impacts of changes in vegetation, soil composition and topography, land use and management.
The erosivity factor $R$ is defined as the mean annual sum of erosivity from individual storms with effective rainfall\(^1\), i.e., rainfall greater than 0.5 inches (about 12 mm). In turn storm erosivity is computed (Angel et al. 2005) as the product of the rainstorm energy ($E$, an empirically-derived function of intensity and depth of rainfall) and the maximum 30-minute rainfall intensity for the storm ($I_{30}$):

$$R = \sum EI_{30}.$$  

(1)

The unit land plot in the USLE erosion calculation is assumed to be only about 20m in length; accordingly, the formula for erosivity assumes that point-wise measurements of rainfall, i.e. rain gauge data, are used. The requirement that we know the maximum 30-minute rainfall intensity adds the need for continuous (or at least very high frequency) measurements. These are stringent requirements that have made the calculation of erosivity a difficult task even in data rich regions such as the continental US (Angel et al. 2005). In response, many approximations to the original formula have been developed in the literature. Typically, point-wise erosivity calculated from the original definition is used to derive an approximate formula that uses temporally averaged rainfall data (from 30 minutes, to annual averages), and the approximation is used for locations with sparser data. A field of erosivity values is then extrapolated from the available data points using other physical variables as added predictors (e.g. topography, annual mean rainfall, average rainfall intensity, or more derived quantities such as the Modified Fournier Index and the Burst Factor that will be introduced below).

The erosivity map for the continental United States that is in use at the Environmental Protection Agency was constructed in such a way (Hollinger et al. 2002; Daly and Taylor 2002; Angel et al. 2005). Annual erosivity could be obtained from the original formula for 1505 stations with 15 minute resolution. When aggregated via a cluster analysis into 9 climatic regions, this erosivity

---
\(^1\) snow is not considered an erosive event
dataset was used as the basis for the storm characteristics and erosivity trends assessment published by Palecki et al. (2005) and Angel et al. (2005). Nevertheless, missing data and inhomogeneities in the length of record made the original R-values unfit as the basis of a continental erosivity map. Instead, they were used to statistically determine an approximation for erosivity that used only daily data. The full daily precipitation time series in stations collocated or nearby the high-frequency gauges were then used to create consistent and complete time series of annual erosivity for the period 1971-2000. Finally, the PRISM spatial distribution method of Daly and Taylor (2002) was used to draw a complete erosivity map: the method combines the available point values for estimated R with the gridded mean annual precipitation at 2.5 arcmin (4 km) resolution, under the assumption that additional information on the spatial field structure of R can be inferred from the spatial structure of P. As explained below, the erosivity map thus produced is used in this study to build our model-based estimate of erosivity and erosivity changes.

Long and complete daily-resolved rainfall time series are still not too common, and many approximate estimates of erosivity that use rainfall records at much coarser temporal resolution have been pursued. Among the indices that use monthly-averaged rainfall data, we focus on the Modified Fournier Index, $F$, introduced by Fournier (1960) and Arnoldus (1980) as

$$F = \frac{\sum_{j=1}^{12} P_j^2}{\sum_{j=1}^{12} P_j},$$

where $P_j$ is the monthly mean rainfall for the calendar month $j$. In this formulation, a month of intense rainfall is seen to create more erosion than the same rainfall spread over a longer time. Quantitatively, though, the link between $F$ and erosivity is not well constrained by observations. Renard and Freimund (1994) proposed a power law for the continental US, but noticed that a quadratic formulation was a better fit for high $F$ values; moreover, more recent estimates of the power-law
exponent for the same region but using different data have found different values (USDA Agricultural Research Service 2013). Outside the US, other formulations altogether have also been proposed (see for example Table 3 in Schönbrodt-Stitt et al. 2013).

Although less used for the US, we also present results using the Burst Factor (Smithen and Shulze, 1982; 1981), as it provides the example of an index that gives more weight to the most intense, and erosive, events. This index, alongside monthly rainfall accumulation, takes as input the maximum daily rainfall for the month. In our formulation, it is calculated as

\[
B = \frac{\sum_{j=1}^{12} M_j P^e_j}{\sum_{j=1}^{12} P_j},
\]

where \(M_j\) is the maximum daily rainfall in month \(j\) and \(P^e_j\) approximates the effective rainfall as the sum of all daily rainfall with accumulation larger than 12mm.

The same requirements that make estimating erosivity from observations a complex task, make it impossible when using climate models. Even the models with the finest resolution compute values for rainfall that are meant to represent averages over hundreds of square kilometers. Moreover, even though models use time steps that are less than 30 minutes, practical storage limitations restrict the temporal resolution archived to 3 hourly at the finest and, more commonly, 6 hourly or daily. Indeed, the volume of data involved in looking at decades of climate simulated by dozens of climate models makes even daily data a challenge to work with. How can we then gain an estimate of the projected changes in erosivity and potential soil loss for the US?

Some past studies have circumvented these restrictions by applying idealized changes in precipitation amounts and intensity (Dabney et al. 2012, for example, ), thus providing results more akin to a sensitivity assessment than a full projection (see also Pruski and Nearing 2002). Others have looked at changes in \(F\), as estimated from monthly mean precipitation changes in a handful
of GCMs (Nearing et al. 2004; Segura et al. 2014), and used the published relationship between $R$ and $F$ to deduce the change in erosivity. Others (e.g., Zhang et al. 2012) have temporally downscaled the GCM monthly output (by linking monthly rainfall totals to the transition probability between dry and wet days and using a weather generator to create daily time series) and used the downscaled precipitation in an erosion model to directly provide estimates of runoff and soil loss.

In contrast to the above studies, this study uses the daily rainfall output from 21 CMIP5 (Taylor et al. 2012) models, bias-corrected and downscaled to 1/8 degree resolution (the BCCDA dataset Maurer et al. 2007, 2014), to estimate changes in erosivity in the continental US under the RCP8.5 emission scenario. Our approach is to duplicate for the models what the literature has done to estimate $R$ where observations of high-frequency rainfall were inadequate. Namely, we estimate the parameters of a statistical relationship between erosivity and daily precipitation from the available data, that is from observations of the 1980-2000 period, and we then use the same relationship to relate the GCMs’ future projections of daily and monthly rainfall to future projections of erosivity changes. Regrettably, the erosivity data available to us is limited to the climatological values; we do not have access to the full time series of erosivity. Ideally, we would estimate the relationship between daily rainfall and erosivity over a subset of the full time series, and use the remainder independent data to validate our results. We acknowledge that a lack of independent validation is a serious drawback. Thus, to overcome this limitation, we also estimate change in erosivity using the F and BF predictors as established in the literature, and we present the full range of uncertainty in our estimates.

The details of the methods used are summarized in Section 2. Changes in the characteristics of rainfall and in other predictors for erosivity are presented in Section 3a, followed by changes in erosivity itself, estimated by different methods, in Section 3b. Section 4 summarizes and discusses the remaining challenges.
2. Data and Methods

a. Overview

This study uses observed rainfall (daily time series for 1980-2000) and erosivity (mean for 1971-
2000) from the PRISM group (Daly and Taylor 2002) on a 1/24th of a degree grid (about 4km). The rainfall dataset has been extensively documented and used (see Daly et al. 2002, 2008, which have more than a thousand combined citations), while the erosivity dataset has been only partially described in the peer-reviewed literature and was obtained courtesy of C. Daly (Oregon State University). The station-based calculations of storm characteristics and erosivity on which the map is based are described by (Angel et al. 2005) and Palecki et al. (2005) as well as in a more detailed report to the funding agency (Hollinger et al. 2002). We summarize here the many steps involved.

First, 23 stations with continuous, breakpoint rainfall measurements (which record the time of significant change in rain rate, together with the value of the change) were used to estimate a correction to the maximum 30-minute intensity $I_{30}$ values obtained from discrete 15-minute averages $(I_{30})_B = 1.034 \cdot (I_{30})_{15}$. Second, for each storm $E$ was computed as the sum over all time intervals (covering the storm duration) of the product of rainfall depth and rainfall kinetic energy (an exponential function of intensity; see McGregor et al., 1995). Third, a transfer function was developed for 1,842 quality-controlled 15-minute stations, linking the storm erosivity values $EI_{30}$ for each rainy day (calculated as above) to the rainfall accumulation $P$. The transfer function has the form $EI_{30} = aP^b$ and the coefficients $a$ and $b$ were computed by least-squares fit using year-round data ($r^2$ values for the regression were reported to be “typically above 0.5”). Note that the regression is based on all storms except those with a return period greater than 100 years—even though snow storms and storms with accumulation less then half an inch of rain are traditionally not included in the calculation of annual erosivity $R$, but very intense storms are. Finally, the
1971-2000 mean $R$ was calculated for daily-resolved gauge data for stations co-located or nearby the 15-minute stations, according to the formula:

$$R = \sum EI_{30} \sim \frac{a}{N} \sum_{n=1}^{N} \sum_{d=1}^{365} P^b_d,$$

where $N$ is the number of years (30 years) and $P_d$ is daily precipitation.

The creation of the gridded erosivity map based on the 1,842 point values of $R$ is described in an unpublished EPA report (Daly and Taylor 2002). In general it follows the PRISM method outlined in (Daly et al. 2002), but using mean annual precipitation for the period 1961-1990 as guidance in the interpolation in regions with significant topography or near coastlines. In flat, homogeneous areas the interpolation acts instead to smooth out differences which were not deemed physical (but instead due to data issues, such as missing data, difference in measuring equipments or period of records, and random noise). The final $R$ field obtained by this procedure has a spatial resolution of 1/24th of a degree, but for comparison to model data, we regrided it to a resolution of one eight of a degree (0.125°). We refer to this observation-based estimate of $R$ as our “target $R$”.

Climate change is estimated in this study from a 21-model subset of the CMIP5 ensemble (Taylor et al. 2012), which has been statistically bias corrected and downscaled to a resolution of one eight of a degree (0.125°) according to the method of Maurer et al. (2007, 2010, 2014). This dataset, known as the Bias-Correction Constructed Analog Version 2 data (BCCAv2), provides the daily precipitation data that is used to calculate present-day and future erosivity in the contiguous United States in the historical simulations and the RCP8.5 scenario. The steps that transform CMIP5 output into BCCAv2 are as follows: GCM output is first regridded to a 2° resolution, then a quantile matching procedure adjusts the rainfall values to match the observed climatology, then a constructed analog technique\(^2\) is used to downscale from coarse to fine resolution. Finally,

\(^2\)An analogue for a given daily weather pattern can be constructed by combining patterns from a library of previously observed patterns; using a companion library of high-resolution patterns creates the high-resolution downscaled estimate.
another step was necessary to correct a dry bias that was reintroduced by the constructed-analog downscaling method: a ratio scaling factor was uniformly applied to correct the annual mean precipitation to again match observation. Note that this rescaling is not expected to correct biases in higher moments of the rainfall distribution. Details can be found in Maurer et al. (2007, 2010).

**b. Rainfall Characteristics**

Figures 1 and 2 present, for observations and the model ensemble respectively, a quick overview of the rainfall characteristics that are most likely to influence erosion: mean annual accumulation, mean daily intensity (defined as the average rainfall accumulation on days when it rains), the burst factor, and the modified Fournier index. The observed characteristics are well known. The western coast ranges receive plenty of precipitation, but otherwise the western states are quite dry; east of the Rockies precipitation is generally more abundant, especially in the South East and in places along the Appalachian range. The same pattern is repeated and intensified in the intensity field, with especially high intensities in the Southeast. Unsurprisingly, both the burst factor $B$ and the modified Fournier index $F$ show a mixture of the accumulation and intensity patterns.

The model ensemble reproduces the annual accumulation and $F$ very well, as expected from the fact that we are using bias-corrected datasets. Instead, the quantities that are based on daily, rather than monthly, data are not at all well captured. Maximum values in the intensity field are muted compared to observations by a factor of at least 4 (changing the threshold for a rainy day from 0 to 1mm/day does not solve the problem, not shown), and the low-intensity also affects the burst factor, especially in the Southeast. This can be explained in part by the lower resolution of the model data, but it seems that the bias correction does not fully address the notorious drizzle bias that plagues GCMs (Dai 2006).
Because of concern with the unresolved bias in daily rainfall intensities, we proceed by estimating erosivity and erosivity changes in two ways: one that is more closely related to the original erosivity calculation (but is affected by the intensity bias) and one that is unaffected by the bias (but for which the formulation of the erosivity calculation is less well motivated).

c. Erosivity Calculations Using Observed Daily Rainfall

Figure 4a shows the target (observed) 1970-2000 annual erosivity. The maximum values are along the Gulf Coast and Florida, and decline further to the north. Erosivity in the western US is extremely low, aside from the mountain regions of the West Coast (note, though, that snow might be contaminating these observational estimates in these areas). Unsurprisingly, the $R$ pattern is reminiscent of both annual mean $P$ and intensity, but some details are different, such as the very high values of $R$ in southern Florida. This pattern differs from that of erosion itself, as steep topography favors erosion in most of the western US (Judson and Ritter 1964) and land-use practices enhance or mitigate the effect of erosive rainfall (Gyssels et al. 2005; Montgomery 2007).

To compare climate models to observations, we would ideally calculate the model erosivity using the same formula that was used in the making of the observational dataset. Unfortunately, this is not strictly possible. The main reason is that the observed coefficients $a$ and $b$ were not reported in the literature. A secondary reason is that we use gridded values of precipitation, and even though the grid of the downscaled dataset is quite fine, coefficients estimated from gauge values may not necessarily be appropriate for a gridded dataset. Still, we want to calculate $R$ from daily rainfall using the same functional form, and in order to do that, we need an alternative way to estimate the coefficients $a$ and $b$ that does not require temporally resolved values of $R$. Our
choice was to exploit the fine spatial resolution of the gridded $R$ dataset, and use that in place of the missing temporal resolution.

For every $1^\circ \times 1^\circ$ square, we take the mean 1970-2000 erosivity and daily time series for the period 1980-2000 (PRISM daily rainfall is not available prior to 1980) and use the 625 grid points in this subdomain to determine the coefficients $a$ and $b$ in the formula $R \approx \frac{a}{N} \sum_{n=1}^{N} \sum_{d=1}^{365} P_d^b$. This provides us with a $1^\circ \times 1^\circ$ gridded map of $a$ and $b$, which we then interpolate linearly to the same resolution as the PRISM data and smooth to the $0.125^\circ$ resolution of the models. In the fitting routine we require that $a$ be positive and $b$ be greater or equal 1 (a choice consistent with the parameter values reported in Hollinger et al. 2002). We want the formula linking rainfall and erosivity to be sufficiently robust to produce a good fit to the target $R$ when applied to rainfall at somewhat different resolution, so we check its performance on the same observational rainfall data, but regridded at the coarser resolution of the downscaled data, $1/8^\circ$. Although this check is not using fully independent data, using data at coarser resolution as input does introduce some degree of separation from the data used in the fit. In the eastern domain, grid points for which the fitting routine selected outlier values (very different from nearby points, but without a clear physical feature to justify the sharp gradient) yielded large errors when the regression was applied to the coarser data. To partially avoid this, we imposed as a search criterion in the least-square fitting procedure that the regression coefficients were bound to be close to the large-scale values over homogeneous areas, and outlier values of the regression coefficients were discarded. This is consistent with the choice made by the PRISM team to use a smooth interpolation in the Eastern US.

Figure 4 compares to the target map the erosivity obtained by regression on the 1980-2000 $1/8^\circ$ daily PRISM rainfall, as well as maps for the $a$ and $b$ coefficients. The exponent $b$ is close to 1 over the eastern part of the States, but it rises above 1.5 in the West. The multiplicative constant
a is most reminiscent of the $R$ and $P$ fields, with values close to 0 in the west (which offsets for the quadratic term in precipitation) and maximum values in the southeast. Figure 4 shows the absolute and relative error between the 2 $R$ estimates. Overall, the regression produces a good match to the original field, but a close look reveals that there are some regional biases. In particular, the West coast has much lower erosivity in the target field than that calculated by the regression; in fact, when looking at the relative error, most of the west appears to be problematic: the errors are small scale and patchy, so the regional bias is not as strong as the local bias, but there is an overall tendency for the regression model to over-predict erosivity.

\section*{d. Erosivity Calculations Using the Observed Modified Fournier Index $F$}

An increase in the intensity of rainfall, especially in the frequency of the most extreme events, is a robust expectation for future climate change, supported by theory (e.g. Trenberth 1999; O’Gorman and Schneider 2009), modeling (e.g., O’Gorman 2012; Tebaldi et al. 2006; Sillmann et al. 2013), and observations (e.g., Alexander et al. 2006; Lenderink et al. 2011), and the effect of such changes on erosivity can only be assessed by using daily rainfall data. For this reason, we have calculated erosivity from daily precipitation, as shown above. Nevertheless, the biases in daily intensity that persist even in this bias-corrected dataset shed doubt on the ability of this method to accurately capture changes in erosivity and, therefore, we include estimates of erosivity obtained from monthly-averaged rainfall data—which was shown above to be close to observations.

Specifically, we calculate $R$ from the modified Fournier index $F$, which is one of the most widely used indices, with an established literature for the US. Renard and Freimund (1994) used high-frequency gauge data from 132 stations to derive a relationship between $F$ and $R$ for the continental
US; the relationship is described by two equations:

\[ R = 0.7397F^{1.847} \]  
(5)

and

\[ R = 95.77 - 6.081F + 0.4770F^2, \]  
(6)

where Eq 5 holds for \( F < 55\)mm and Eq 6 holds for \( F > 55\)mm and \( F \) is defined as in Eq 2\(^3\).

Reinard and Freimund found that neither relationship could be applied to the stations of Washington, Oregon, and California because winter snow was coming into the calculation of \( F \), but should not contribute to \( R \). Their criterion to exclude such stations was that no month between October and April should contribute more than 15% to the annual accumulation. We have followed the same, quite arbitrary, criterion.

Other scholars have found different relationships for other locations (see the many examples reported in Schönbrodt-Stitt et al. 2013), both linear and of the form \( R = aF^b \), and the literature repeats Arnoldus’ recommendation that relations obtained using the modified Fournier index should be applied only to locations within homogeneous climatic regions. Therefore, we also apply the same method described above for daily precipitation and estimate local \( R \) to \( F \) relationships for points in each 1°x1°square, allowing for both a linear and a power law relationship. Thus, we have three ways of estimating \( R \) form \( F \).

Applying Equations 5 and 6 to the gridded PRISM data leads to overestimating the erosivity everywhere in the US, with the only exceptions of eastern Texas and Florida (Figure 3c). The fact that the error is of the same order of magnitude as \( R \) itself is not inconsistent with the errors shown by Reinard and Freimund (see their Figure 3b), but the positive bias in the estimate is harder to explain. Nonetheless, we note that the relationship between \( F \) and \( R \) in the literature

\[^3\]Note that these are the equations reported in the figures. The main text in Reinard and Freimund contains a graphical error in Eq 5, and subsequent citations in Nearing (2001) and Segura et al. (2014) contain a typo in Eq 6.
for many world regions is often linear, and, as will be shown below, the local-regression methods suggest a much weaker dependence on $F$ than the Reinard and Freimund’s formulas in all but a few mountainous regions of the US.

To determine the $F$ to $R$ relationship from local regressions, we have tried several functional forms: a linear relationship, a power law, the sum of the two, with and without subjective bounds on the coefficients. Here, we present results from the linear and power law functional forms. Nonetheless, we imposed an additional regional constraints to avoid small-scale noise in the coefficient fields: the noise was deemed unphysical and it gave rise to large local errors when the fit was applied to the 1/8° PRISM data. In particular, we have imposed that the relationship between $F$ and $R$ stays close to linear in the Southeast. This trial-and-error fit without a-posteriori verification would be problematic if we were to claim that it proves a physical connection between $F$ and $R$. But our goal is much more modest: we assume that a relationship between $F$ and $R$ exists, as established in the literature, and simply obtain a scaling between the two quantities that performs better than Reinard and Freimund’s formulas.

The end result of the local regressions are presented in and Figures 3d,e, 5, and 6. The case of a linear fit provides the best fit (Figure 5): the errors are small and very patchy, indicating that there are weak regional biases in the estimate of the erosivity field. The power law produces errors of larger magnitude, and their severity is worst in the western US. Here, the power law coefficient sets a stronger-than-linear relationship between $F$ and $R$, and the end result is a regression that over-estimates erosivity. In both the linear and non-linear cases, the local regression allows us to calculate erosivity for the entire domain, including the West Coast, but errors there are larger. Moreover, the issue of including snow in the erosivity calculation is not properly addressed by any of these methods, although changes from snow to rain might indeed be an important factor in determining future changes in erosivity.
$R$ is better approximated using $F$ than with the daily precipitation. This is somewhat surprising, given that it is the daily precipitation that goes into the original $R$ calculation. On the other hand, it might be that the use of annual mean rainfall in the interpolation of $R$ from point measurements to the gridded field introduces a bias in $R$, making the field more similar to rainfall accumulation than it would otherwise be.

e. Erosivity Calculations Using Historical Model Data

When applied to the model ensemble daily rainfall data for the 1980-2000 period in the historical simulations, Equation 4 with the coefficients of Figure 4 yields a very reasonable pattern of erosivity (Figure 7a), but with obvious biases. The absolute error is large along the West coast, but comparable to what is obtained by using observed daily rainfall for the fit (see Figure 4), and also large in the southeast, where erosivity is overestimated by the regression by 10 to 40%. This is somewhat surprising, given that in the same region the models underestimate rainfall intensity; yet, in this region the relationship between rainfall and $R$ is very close to linear, so it is possible that the positive bias in the number of rainy days (given that the mean has been corrected, low intensity must go together with high frequency) translates to the overestimation of erosivity. While the relative error in the eastern US is only prominent in Florida and coastal regions, it is large everywhere in the west. Nonetheless, here the error pattern is as patchy as was seen for observations in Figure 4, so that the overall regional bias is not as severe. The western US is also the region for which there is more scatter across the model ensemble, as signified by the intra-ensemble coefficient of variation (the standard deviation of the inter-model spread, divided by the multi-model mean erosivity, 7b).

When we calculate erosivity from the models’ $F$, we obtain somewhat better results. Similar to what is seen for the observations, the linear relationship captures $R$ with the least bias, while
the non-linear relationship induces a worst overestimation of erosivity in coastal regions of the
Gulf and the Southeast and in the western US. Erosivity in the Great Plains tends instead to be
underestimated by the models. The biases in model-estimated erosivity are all qualitatively quite
independent of the formula used to calculate the estimates, but they are smallest when $R$ is linked
linearly to $F$, as one would expect from the fact that monthly rainfall (and thus $F$) were the target
of the bias-correction.

3. Projections

a. Rainfall

Figure 10 shows the end-of century projections for annual rainfall accumulation, mean daily
intensity, the burst factor, and the modified Fournier index. All four fields show overall future in-
creases over most of the North American continent. The annual precipitation signal in the northern
part of the domain (Canada and US) is clearly positive, with anomalies replicated across the en-
semble (stippling indicates 15 or more of the 21 model agreeing on the sign of the anomalies), but
in the southern part of the domain the anomalies are weak and not very robust. Although barely
significant (see the limited extent of the stippling), there is general drying in Mexico and Texas, ex-
tending into the Southwest US, and more positive anomalies in the eastern Gulf and Florida; This
is consistent with the expectations reported in the literature for both CMIP3 and CMIP5 models
(see for example Seager et al. 2007, 2014; Biasutti et al. 2011; Christensen et al. 2013; Maloney
et al. 2014). The positive anomalies in Arizona are not expected. They are a consequence of
the bias-correction method: the projections for the same 21 runs in the original CMIP5 ensemble
show that the negative rainfall anomalies do extend farther north than their downscaled counter-
parts. On the other hand, there is no significant difference between using only 21 runs from the
native resolution CMIP5 ensemble, and using 79 runs from 38 models in the CMIP5 ensemble (not shown).

The intensity signal (see also Wuebbles et al. 2014) presents a similar pattern of stronger positive signal in the north and along the coasts, but in this case the region of consistency across models is more expansive across the US, with only the Colorado Plateau and the southern Great Plains not showing a robust increase in intensity (anomalies are nonetheless positive).

The modified Fournier index is more robustly positive than the annual accumulation, from the East coast to the Mississippi and from the West coast across the Rockies. The southern Great Plains show negative change in $F$, but the anomalies are inconsistent across the ensemble. Also, $F$ increases at the Gulf Coast even though mean annual $P$ declines here, a difference caused by an increase in monthly intensity that dominates over the mean drying. The strengthening of the robust pattern of anomalies in $F$ compared to annual rainfall is an indication that the seasonal cycle of rainfall will be getting more peaked, i.e. more rain in the rainy season.

Changes in the burst factor $B$ are the most uniformly positive. $B$ values reflect changes in both mean rainfall and rainfall extremes. This is especially true given that we have calculated the effective rainfall entering $B$ using the observation-derived threshold of half an inch, which corresponds to higher rainfall percentiles in the models. Moreover, the maximum daily rainfall for the month enters the calculation directly. The domain-wide robust increase in $B$—extending farther than either mean rainfall or mean intensity—is consistent with the expectation that the intensity of extreme rainfall events will increase more than average rainfall and average intensity.

Given the pattern of robustness and uncertainty in the predictors of erosivity (that is, in mean annual rainfall, daily intensity, $F$ and $B$), we can expect that erosivity changes will be generally positive, but quite uncertain in the southern and central US and dependent on the method used
to estimate erosivity from rainfall. In the following section we look at such changes in a more
quantitative way.

b. Erosivity

Figures 11, 12, and 13 show the multimodel mean difference in erosivity between the 1980-
2000 and 2080-2100, both in erosivity units (MJ mm ha$^{-1}$ h$^{-1}$ year$^{-1}$, top panels) and in units
of % of the 20$^{th}$ century values (bottom panels), alongside the intra-ensemble scatter in the same
quantities. In Figure 11, $R$ is estimated from the daily precipitation values, while in Figure 12 and
13, it is estimated from $F$, either through a linear or through a non-linear regression, as described
in Section 2.

As would be expected from the rainfall changes, the models suggest an overall increase in ero-
sivity across the US, but the details of the projections change quite significantly depending on the
method used to estimate $R$. When daily precipitation is used, the increase in erosivity covers the
west, east and north central U.S., with negative anomalies in Texas and north into the Colorado
Plateau. Conversely, the estimates obtained from the Modified Fournier index would indicate pos-
itive anomalies in Texas (as in most of the domain) and only a region of very weak decrease in
erosivity further north around Colorado and Kansas.

These patterns match very closely the patterns of the erosivity predictors (rainfall changes and
$F$), indicating that non-linearities have a weak role in setting the erosivity anomalies. For $R$ using
daily data the changes are primarily driven by the changes in mean accumulation. For $R$ calculated
via $F$ changes in monthly intensity are more important and there are regions where $R$ increases
even as accumulation declines, because an increase in monthly intensity dominates.

In spite of the overall uncertainties and biases in the model estimates, it is nonetheless clear that
the expectation of increased erosivity for most of the US is supported by this analysis, and that
strategies to prevent soil loss will need to be implemented in a variety of environmental conditions, from the mountains of the West to the northern Great Plains, to the Appalachian Range and the Eastern Seaboard.

4. Conclusions

Changes in soil erosion have many drivers and a full evaluation of the effect of climate change on soil loss and sediment deposition can only be achieved by a truly integrated assessment that takes into consideration changes in vegetation and land use. At the moment, the coupling of climate, vegetation, and landscape dynamics at the scales relevant for erosion is not yet achievable, and an assessment of erosion risks under global warming must, by necessity, take a simplified approach. Here, we focus on the one driver of erosion most directly related to climate: rainfall erosivity.

The purpose of this study was to provide an assessment of the projected changes in erosivity for the continental United States, based on the most up-to-date projections of climate change. We have used downscaled rainfall projections from 21 climate models from the CMIP5 archive to estimate future erosivity changes. To estimate erosivity, we have used both daily rainfall values and the modified Fournier index—which is based on monthly rainfall accumulation—and derived the scaling relationship between rainfall and erosivity from observational estimates of both. While daily rainfall maps are available for the period 1980-2000, only the mean value for the 1971-2000 is available for erosivity. Such a dearth of data hinders a robust estimate of the relationship between rainfall and erosivity, and introduces another large source of uncertainty in the estimate of future changes, comparable to that due to the spread in climate projections across the CMIP5 ensemble.

Overall, we confirm that the general expectation of worsening erosivity under climate change is correct, but uncertainty is large in large swaths of the United States, especially in the South.
and in the interior. When erosivity is estimated from daily rainfall values, the multi-model mean indicates a decrease in Texas and the southern Plains, while an increase in erosivity is simulated by a majority of models when the estimate is done using monthly precipitation. The pattern of erosivity change estimated from change in $F$ is consistent with what was found by Segura et al. (2014) using just 3 models (with 3 scenario each) from the older CMIP3 archive. This consistency indicates that uncertainty in the method of estimation of $R$ is more consequential than that derived from the spread in climate simulations.

A more quantitative assessment will remain a challenge, hindered both by model deficiencies and by lack of complete erosivity records from observations. Ameliorating the biases in the representation of rainfall intensity in climate models is bound to help, and the task is already on the modelers’ agenda. So is the need for reducing uncertainty in the projections of regional climate change. But the uncertainty stemming from the relationship between rainfall and erosivity could be ameliorated without having to wait for progress in climate models. Progress could be made by recalculating erosivity time-series from high quality gauges, and high-frequency, high-resolution satellite estimates of rainfall, so that a more detailed and more reliable record of the connection between daily rainfall and erosivity can be established for the entire US.

Acknowledgments. We gratefully acknowledge NSF support through award AGS12-43204. We thank Dr. Daly and the PRISM group for the erosivity and rainfall data. We acknowledge the World Climate Research Programme’s Working Group on Coupled Modelling, which is responsible for CMIP, and we thank the climate modeling groups for producing and making available their model output. For CMIP the U.S. Department of Energy’s Program for Climate Model Diagnosis and Intercomparison provides coordinating support and led development of software infrastructure in partnership with the Global Organization for Earth System Science Portals. Haibo Liu
and Naomi Henderson were instrumental in accessing and organizing the data. We also gratefully acknowledge the use of the downscaled CMIP5 Climate and Hydrology Projections archive at http://gdo-dcp.ucllnl.org/downscaled_cmip_projections/
